These results are not at all meant to give absolute factors of hygrosorptive power, but merely to show that this power varies greatly in different manures. For permanent comparisons probably a standard cup would have to be adopted with various other fixed conditions; but into this point I need not here enter.

THIRD SERIES.

The manures for the third series of comparisons were completely sun-dried and pulverised, and turned over in a current of air under bright sunshine till all the moisture which could be driven off in this way was got clear of. The pans were then loosely filled, and the surfaces evenly struck off. For each kind of manure there were two pans of different sizes; all the No. 1 pans being largest and of the same size, and all the No. 2 pans being also equal to each other. They were then placed in a tray and set in the floor of an outhouse. The door and window permitted a constant current of air over the pans; but they were completely protected from all rain. They were exposed from June 13 till July 30, and were weighed sixteen times. The weights of dry manure are made 100, and the increase in each case is reduced and stated percentively as before.

Notes were kept of the state of the weather, which was sometimes dry and sometimes wet, but not much rain fell during the time under notice, so that the air was in an average state of saturation. It was not thought fit to continue the experiment longer, because large crops of mould began to show themselves on some of the pans, especially those containing the Turnip and Potato manures; and, as many fungi have a strong affinity for moisture, further results would have been vitiated.

The manures are placed in the table in the order of their absorptive power, and it will be seen that the soil has absorbed 3 per cent, the ground coprolite 5, the cow-dung 16, the dissolved coprolite 25, the Challenge manure 37, the Turnip manure 39, the guano 53, and the Potato manure 92 per cent. The earth, under the conditions of atmosphere which here affected the experiment absorbed in a few days all the moisture it was capable of withdrawing from the air, and the ground coprolite behaved in a nearly similar manner. The cow-dung after July 15 gave off a little of the water it had up to that date absorbed. The superphosphate continued absorbing at a diminishing rate up to the end. The Challenge manure, Turnip manure, guano, and Potato manure, also went on to the end adding to their water, at a rate, upon the whole, gardually diminishing, the guano having added about one-half to its weight, and the Potato manure having nearly doubled its weight. —*Gardeners' Chronicle.*

EXPERIMENTS WITH THE ELECTRIC LIGHT.

It is really a matter of the greatest importance in vegetable physiology to ascertain precisely what is the effect of growing a plant under continuous light. The prevalent notion among physiologists is that light retards growth—that a plant feeds by day by virtue of the sunlight, and uses up at night the food so gained, or rather that which has previously been so gained and stored in the tissues. At first sight it seems as if this opinion must be in direct contradiction to facts that come under our daily observation—that it must be directly contrary to what is observed in the short summers but nightless days of the far North, where for a few weeks the plants are constantly exposed to light, and where, in consequence, growth are harvest operations occupy a much shorter time than with us. It would seem also that the results already obtained by the aid of the electric light are directly contradictory to the opinion of the physiologists. But the divergence is not so great as it appears. Laboratory experiments are one thing, ordinary cultural experiments are quite another. It is the object in the laboratory, as far as possible, to study the influence on plants of light only, or of heat only, or of moisture only, to isolate each factor of a plant's growth, and study it by itself—see what it does, and what it does not do when separated from other agencies. In Nature, or under ordinary cultivation it is quite another matter. All the forces of Nature come into play, and fashion the plant by their combined influence. The action of light is controlled by that of heat and moisture, and so the plant is the result of the concurrent operation of many forces, and it varies in character and in the way it does its work according as it is equally or unequally influenced by these agencies. It is rash at present to speculate, still more so to dogmatise, as to the absolute necessity for rest in plant-growth—we know how desirable it is sometimes—rash to affirm that periods of darkness are absolutely essential to their health. On all these points we want accurate information, and should welcome it from any source. For immediate practical purposes we need not, however, be so exacting It is for early forcing purposes, as we have before said, that we imagine the light will be found most useful. It is now established sufficiently that the light, properly applied, will supplement the daylight and afford light when the sun does not, and that in so far it will hasten vegetation and promote the more rapid ripening of fruits. But whether it will do so at such a cost as to allow of commercial success is a point that has not yet been satisfactorily answered.—*Gardeners' Chronicle.*

NEW PRODUCTS.

SIR,—Perhaps it may be interesting to you to know the degree of favour in which the several new products are now held, as judged by the demand for seed and price of the different sorts.

Liberian Coffee.—I am sorry to say this once much run after article is now (most undeservedly I think) at a discount. There is no irland demand for seed, and even good nursery plants are unsaleable. I have heard of only one enquiry lately. It was from a part of Dumbara, which, I fear, is too dry for the proper maturing of Liberian coffee fruit. I should like to see another letter from Udapolla, on the relative merits of Liberian p'ants and *stumps*. I know the experience of some differs from that of Mr. Jardine. Another point which should be settled is, whether it be true that Liberian trees do not fruit in their 6th year. Whether true or not, some believe it, and I have even heard the Peradeniya garden authorities quoted as being of this opinion. It is a pity this product should be viewed with distrust, as it is undoubtedly a sturdy grower, and adapts itself to old soil in a wonderful manner.

Tea.—There is a great demand for seed of the Asasm-hybrid variety, but very little faith in the seed generally sold as such. I am glad to see one firm advertising that the seed they sell is from selected trees. But query! is there not the danger of some crossing with the inferior qualities adjoining? For, although not allowed to grow up unpruned, as is the case with plants reserved for seeding purposes, it is well known that the inferior kinds are given to flourishing much more freely than their better class neighbours. I cannot help thinking that there is source of much and easily acquired gain open to any one who will isolate a few acres of really first-class tea bushes, and allow them to seed. Men would much sooner pay R80 for undoubted seed, than pay R40 for a mixed lot. At present, those who have seed, cannot meet the demands made upon them, and the public owe the growers thanks for selling at the comparatively low prices of R40 to R50. There is no doubt the up-country faith in coffee has been rudely shaken within the last six months, and planters as well as V. A.'s are beginning to see that cinchona will not grow everywhere. Were the money available, there would be a great rush into tea in old districts. Every estate ought to have a few acres of a fine variety, if only as a nursery for future requirements. The day will come when cinchona will become *rare* on most estates; and as it has to be rooted out, *something* (and tea is the only alternative I know of at present) must take its place, unless European industry is to retire from the hills.

Cinchona.—There is not much activity just now in cinchona seed or plants. Not that there is no *demand*, but that there is no *supply*. Officinalis seed might be gathered literally by the ton, but bitter experience bids us leave it alone. Plants can be had for R2 per 1,000 instead of the R20 of a year or two ago. *Succirubra* trees are not seeding much at this season, but there will be plants by-and-by. Many have been shaved, and people are shy of seed from such trees; most have been lopped, and it is from the lower branches that seed is chiefly obtained. There an unlimited demand for plants. R20 per 1,000 can be readily got for Succirubra or Hybrid plants, but nurseries were few this year, and have long ago been disposed of. There are some coming on for N. E. planting. Natives are now keen purchasers, and strange to say *for cash* too. *Ledger* seed of all kinds is not much trusted. This especially applies to imported seed. When Mr. Taylor again sends seed from his trees into the market, he will find by the ready sale it will command that planters generally appreciate the care bestowed by him on the selection and gathering of it. Of his seed I have heard no complaints; of imported seed I have frequently seen and felt the unhappy results. If Mr. Smith went round the country and examined nurseries grown from "*undoubted Ledgers* of high analysis," he would speedily become a believer in sporting and hybridization.

Cocoa Seed is now comparatively very cheap, as there is any amount to be had. The reasons why the extension of this product is so slow, are: 1st, that there is no land being sold which is suitable to it,—I might go further and say that *it is believed* there is not much land in the Government hand which is well adapted for it. Were it not so, there would be many applications, for belief in the product is strong. 2nd, in old soil, cocoa is probably the most perplexing and disheartening thing planters ever touched. Its enemies are like the stars in the firmament, and planting, supplying and resupplying are often done with very small results. Perhaps the best method is to put a few seeds into each hole at stake. 3rd, as trees get up to four and five years of age, the returns are much beneath the expectation. All blossom copiously, but only one tree in ten sets and retains its fruit. It is now quite certain, especially in the case of old soil, that patience will be sorely tried before fortunes are made in cocoa. But patience *will* be rewarded, and a cocoa estate can be handed down to posterity.

Rubber has been under a cloud, from which Dr. Trimen's recent revelations should tend to rescue it. It is being slowly extended in a cautious and experimental fashion, and I predict a sudden change of feeling and its exhaltation into a favorite. Seed is now a *drug*.

Cardamom is the popular king of new products wherever there is land to grow it, and the money wherewith to buy the bulbs. In the northern districts it reigns supreme, although it has great difficulty in taking possession of much territory, from the great scarcity of bulbs and the immense price they command. Even natives pay Rs.50 per 1,000 for single bulbs, and if owners refuse to sell they take them *by stealth*. I heard recently of one case, in which a small clearing was completely robbed of its bulbs in a single night. Belief is beginning to spread that shade is not nescessary for cardamoms, or if so, that the shade of cinchona trees is sufficient. I even learn that the oldest shipper of cardamoms is now planting in the open.

The chief requisite for this product is *good soil*. It will grow almost anywhere; but on a poor soil fruit will be deficient. Can any one give us an idea of the probable future market for cardamoms?—NEW PRODUCT.—*Times of Ceylon.*

INDIA: CROP AND WEATHER REPORT.

(For the week ending 8th August, 1882.)

GENERAL REMARKS.—The very heavy rainfall in the extreme south-west of the Madras Presidency and in Coorg has somewhat diminished, although still heavy. In other parts of the Madras Presidency it has continued to be light, except in Gaujam. In Mysore rain fell in varying quantities in all districts. In the Nizam's Territories only light showers occurred. In Berar the rainfall was good. In the Bombay Presidency it was good in some districts and deficient in a few. In the Central Provinces it was generally fair, though heavy in some districts.

In Central India and Rajputana the rainfall was good in some States, light in others, and a break occurred in a few States. In the Punjab there was rain in all but four districts, light, except in Amritsar. In the North-Western Provinces and Oudh good rain fell everywhere, excepting one or two districts. From Bengal rain in varying quantities is reported from all districts. In Assam and British Burma good rain fell in all districts, except Prome.

Agricultural prospects are favourable in both these Provinces; ploughing, sowing, and transplanting are progressing. In Bengal more rain would be beneficial in many parts for autumn crops and the winter rice. In the North-Western Provinces and Oudh the prospects of the kharif crops are generally favourable, but here also more rain is needed in some districts. In the Punjab sowings have been completed or nearly so, and prospects are good here as well as in the Rajputana and Central India States. In the Central Provinces a break in the wet weather is still needed for weeding operations in some districts; prospects of the kharif crops are favourable.

In the Bombay Presidency sowings have mostly been completed and rice is being transplanted in some parts; more rain seems wanted in the Deccan. In Berar the cotton and *kharif* crops are in good condition. In the Nizam's Territories also crops are in good condition, but more rain is needed. In Mysore wet cultivation in some parts requires more water, while in others excessive rain has done some damage; but on the whole prospects are favourable here and also in Coorg. In the Madras Presidency standing crops are, with a few exceptions, in fair condition.

The barometer had risen in all parts of Northern India and in the central and western parts of the Peninsula up to the 9th instant, but a slight fall set in on the 10th.

The break in the rains, however, continues in North-Western India, where dry weather has set in. Atmospheric conditions somewhat resemble those of August 1880.

MADRAS.—General prospects fair.

(ASSAM) Cachar.—Weather cloudy; prospects of tea, *dumahi* and *murali* crop satisfactory; transplanting *sali* crop continues; common rice 25½ seers per rupee; public health good; death of 6 cows by cattle-disease reported from Lakhimpur.

MYSORE AND COORG.—Rain continues to fall generally throughout the Mysore state, and at others excessive rain has done some damage and is retarding the transplanting of seedlings; in Kolar the rain has been scanty; crops generally in good condition and prospects are favourable; small-pox, fever, and murrain prevail in many places; prices satisfactory.—*Pioneer.*

ECONOMIC PRODUCTS OF PERNAMBUCO.—Writing on the trade of Pernambuco, Mr. Consul Bonham says the chief products are sugar and cotton—the former being grown on all the lower lying ground and in the valleys, while the latter is chiefly grown in the distant interior. Coffee is grown in small quantities, and in former years a little was exported, but it has not been found to answer since owing to the climate. It does not produce fruit at any regular season, but does so more or less all the year. This is found to be a great hindrance to growing it in large quantities, though for private consumption a fair amount is produced. It is stated that there is land in the interior, where the climate is somewhat cooler, which is well adapted for the cultivation of coffee. Eventually when the interior is opened up, it may be found to succeed and become an important product. On the subject of cocoa it is stated that attempts are being made to introduce its cultivation, and large plantations are in course of formation. It is probable that it could be cultivated successfully, and in future years it will most likely rank amongst the staple products of the country. Large plantations of the cocoa-nut palm exist near the sea, but the nuts are not exported in any quantity; some, however, are sent to the south of the empire. A large trade might be done in this article. Tobacco is grown in the province, but not in a sufficient quantity to meet home requirements, since much is imported from Bahia. There is no reason why the cultivation of this article should not be immensely increased, as the country is well suited for its growth, and it is very surprising that it is not more extensively planted, not only in sufficient quantity to meet home requirements, but also for export. The castor-oil plant (Ricinus communis) is described as growing very luxuriantly, but it is not cultivated to any extent; some of the oil is, however, prepared and used in lamps.—*Gardeners' Chronicle.*

JAMAICA CROWN LANDS.—I should be much obliged if you or some of your readers can afford me the following information as to the Government or Crown lands for sale in Jamaica. I have been referred by the Colonial Office to Edward Stanford and Co., the publishers of the "Colonisation Circular, 1877," but Mr. Stanford writes to say that the circular is out of print, and it is, at best, doubtful if it contains what I want to know. I have tried Messrs. Silver and Co. and several others, but without success. The Colonial Office also referred me to the Colonial Secretary, Jamaica, but it takes six weeks to get an answer back. As you published some very interesting letters *re* Jamaica, perhaps you can tell me: 1, the price; 2, the locality; 3, if any are for sale on the north side near the sea; 4, if any special terms for taking a large lot.—H. R. [We fear H. R. must be satisfied with doing as others have to do, viz., apply to the Director of Roads, Kingston, Jamaica, who is the appointed officer for land grants. The upset price of Government land is 2s. per acre, subject to terms as to planting, timber, reservations of roads and springs, and incidental surveyor's fees, &c., and it is sold by public auction. There are from 60,000 to 100,000 acres of untouched virgin forest on the mothern slopes fit for coffee, and a corresponding area of higher elevation available for cinchona. The actual cost per acre varies, according to accessibility and character, from 4s. to £3 per acre; the average price of large tracts is seldom above £2 or £3 per acre.—ED.—*Field.*]

HINT FOR SEED-GROWERS.—Dr. Aitchison, in his paper on the *Flora of the Kuram Valley*, tells us that the leaves of Edwardsia mollis and of Adhatoda vesica are largely collected and mixed with the grain in the rice nurseries to hasten the process of germination by the heat generated during their decomposition.—*Gardeners' Chronicle.*

CULTIVATION OF MEDICINAL PLANTS.—Great differences are known to exist in different species or varieties of the same genus as to their medicinal properties—a fact which every one familiar with the varying qualities of Apples and Pears will readily understand. The species of the large genus Aconite, for instance, differ very materially one from another in the quantity of aconitin they contain, and even in the quality and strength of that ingredient. For medicinal purposes it is specially desirable that, so far as possible, uniformity of strength in this and other drugs should be attained. With a view, therefore, to ascertain which particular variety is best for the purpose, it is suggested by the *Pharmaceutical Journal* that space should be afforded at Kew for the cultivation on a sufficiently large scale of various species of Aconite and other medicinal plants, which it is not possible to obtain free from other species in commerce, to allow of chemical investigation of the quantity of the alkaloids contained in the various organs at different parts of the year. Such work is indeed quite legitimate for a botanic garden, and formed one of the duties of the old "physic gardens." The importance of determining the right variety is exemplified in the case of the Cinchonas, where at one time much time and money was lost in cultivating inferior varieties. It very often happens that two varieties, scercely differing at all in external appearance, yet vary so much in chemical constitution that the one is practically useless, while the other is rich in some particular secretion which renders it of consequence for commercial purposes.—*Gardeners' Chronicle.*

THE POTATO DISEASE.—Potatos, generally, and early varieties especially, must be nearly fully grown before the disease will attack them virulently, and where cottagers in particular often lose their crop is in the disease commencing in the early ones, and spreading at once to the late sorts, planted by the side of them. They would to a great extent save their crops if they could only be induced to remove the haulm off the early varieties, as soon as the first spots are observed, and destroy it. [We have often urged the necessity for this procedure.] Those who take every precaution against the disease do not get all the reward they should, so long as their neighbours remain indifferent in the matter, as a garden wall will not keep the spores out. When the disease is not spreading rapidly and the tubers have not attained a fair size; it is a good plan to go through the rows and remove all the affected leaves. We saved a large patch of American and other varieties, which are generally so badly affected by the disease, in this manner last year.—*Gardeners' Chronicle.*

CURIOSITIES OF GRAFTING.—The paragraph headed as above, in your impression of July 1, reminds me of a successful experiment which I made some twenty years since, and which I think is of sufficient importance to be again brought before the lovers of conservatory climbers. Having at that time a Passiflora edulis covering a large portion of the back glass work of a warm house, I conceived the idea of working (by inarching) a few varieties of showy Passion-flowers and Tacsonia upon it, for the sake of variety. Consequently I procured the necessary growing shoots of the current year, and at once performed the operation of inarching them upon the P. edulis, allowing the end of each scion to dip into a phial of water, suspended for the purpose. When the operation was completed a garden mat was suspended at a short distance in front of the plant, as a shade, and this was kept moist by heavy syringings. The number of scions inarched was about ten or twelve, all of which grew and flourished until the following winter, when, owing to some accident to the stem, the old plant died. Had not this happened, I doubtless should have had, in the following spring, Passifloras, and Tacsonias of all colours mingling upon the same plant.—H. H. [We have often urged the budding or grafting of various Passifloras and Tacsonias on a hardy stock. ED. *G. C.*]—*Gardeners' Chronicle.*

LAGERSTROMIA INDICA.—The display of flowers which this plant is capable of yielding under a proper system of cultivation is now practically exemplified in the fine garden of Joshua Dickson, Esq., Winslade, near Exeter, where there are plants flowering over 8 feet high and as much across, literally laden with a glowing mass of rich rosy-pink flowers, produced in long panicles, something after the manner of Hydrangea paniculata grandiflora, but much more graceful-looking, because the flowers are not so closely packed together upon the flower-stem. Plunged in a border in the conservatory, under the broad leaves of Palms or Fern fronds, the effect is magnificent—probably there is no other plant coming into flower at this season to equal it for general decorative purposes.—*Gardeners' Chronicle.*

BAD NEWS FOR PORT WINE DRINKERS.—Official papers state that the pest of the Phylloxera vastatrix, which had manifested itself in the Douro Vines in a virulent form, has invaded the districts of Leiria and Santarem; and it is anticipated that ere long the whole country, as far as the Algarve, will be infested with this insect. The treatment of the Vines with sulphate [ide] of carbon has not proved effectual, so much so, that in the Douro the cultivation of Tobacco is going to be tried with the permission of the Government. Moreover, in spite of the conventions entered into by Portugal, and the regulations issued, the auction of the authorities with regard to the Phylloxera is marked by very great apathy. It is stated that the Botanical Garden at Coimbra has long been infested with the Phylloxera.—*Gardeners' Chronicle.*

A PEACH TREE AT BEARWOOD.—A truly remarkable example of a Royal George Peach may be seen in one of the Peach-houses at Bearwood. It completely fills the interior of the roof of a lean-to house 20 × 14½ feet. The tree is in the best possible condition; it could not well be more vigorous in growth and healthy in appearance, and the stem is in proportion to the tree, and of the same thickness throughout. The crop of fruit, now rapidly reaching on to ripeness, is very large, and individually the Peaches are of splendid development. It is a crop much above the average, but the tree is in such perfect health and so robust in all its parts as to be able to carry it to a most successful issue. Mr. Tegg wins high honour over the management of this splendid tree, and the achievement well deserves a record. It is when one looks on to the tree through the glass from the outside that the amount of the crop is realised. It may be added that the Early Grosse Mignonne is regarded by Mr. Tegg as the best early Peach in cultivation.—*Gardeners' Chronicle.*

NEW METHOD OF GROWING AND TRAINING TOMATOS.—As we grow older the majority of us are supposed to grow wiser in our generation, and if we do not we certainly ought to do. At all events, in the matter of Tomato growing we have not been over-sharp in discovering the shortest way of obtaining the best results. As long as Tomato growing was carried on chiefly by private gardeners the one-leader system, which gave a few fine fruits, was all very well for the exhibition table, and ornamental-looking in the hothouse of a private gentleman; but as the public demand for English-grown Tomatos increases, the one-leader system will have to be given up, and the side-shoots more depended upon for a general crop. As a matter of fact the side-shoots are the most prolific, and if they do not bear the largest fruit, they produce the greatest quantity, and already the market-growers, or the most knowing of them, are finding this out, and are very wisely altering their tactics. In the case of one—a well-known private gardener at one time—the system now adopted is to plant out in a narrow border (there are Cucumbers grown at the front of the same house), and peg down the side-shoots upon the surface of the border, where they root in a short time, and have to be supported under the weight of their crops. Instead, therefore, of having long naked stems, we shall in future have a border covered with medium-sized shoots, and laden with fruits which pay as well, or better, than anything else in the market at the present day. Given a moderate-sized variety, and a free cropper, grown upon the principle indicated, and started early in the season, or even now, for a late crop, no other garden produce will be found to pay its way better, or be more generally satisfactory.—*Gardeners' Chronicle.*

THE ELECTRIC LIGHT.—The theoretical possibility of imitating, by artificial means, the effect of solar radiation on plant-life has been demonstrated again and again. In obtaining experimental results on a large scale there seems to me absolutely no difficulty except the question of cost. I see no reason why, say, Cucumbers, should not be grown with electric light alone, if proper precautions are taken to exclude the nitrous gases and prevent scorching. The only question is, whether the result will justify the expenditure even to the wealthy. Dr. Siemens speaks of the importance of excluding the ultra-violet rays. That they are positively injurious to plants supplied with an adequate amount of light of lower degree of refrangibility has, I think, not been demonstrated, though no doubt these rays are filtered off to a great extent from sunlight by the aqueous vapour present in the atmosphere. Any positive results in this direction would undoubtedly be of the greatest interest.—W. T. THISELTON DYER.—*Gardeners' Chronicle.*

THE UTILISATION OF ANTS IN HORTICULTURE.—Professor Riley contributes the following note to a recent number of *Nature*:—Dr. C. J. Macgowan has sent me, from Hanchow, Province of Hainan, China, a little paper on the 'Utilisation of Ants as Insect Destroyers in China.' It seems that in many parts of the Province of Canton the Orange trees are injured by certain worms, and to rid themselves of these pests the inhabitants import ants from the neighbouring hills. The hill-people throughout the summer and winter find the nests of two species of ants, red and yellow, suspended from the branches of various trees. The 'Orange ant breeders' are provided with pig or goat bladders baited inside with lard. The orifices of these they apply to the entrance of the bag-like nests, when the ants enter the bladders, and, as Dr. Macgowan expresses it, 'become a marketable commodity at the orangeries.' The trees are colonised by placing the ants on their upper branches, and bamboo rods are stretched between the different trees, so as to give the ants easy access to the whole orchard. This remedy has been in constant use at least since 1640, and probably dates from a much earlier period. This is certainly a new way of utilising ants, which, as a rule, are deservedly considered a nuisance by the horticulturist. Professor Riley would like to learn from any reader whether the facts communicated have before been known in Europe, and, if so, whether the species of ant has been determined."—*Gardeners' Chronicle.*

THE ORANGERY.—It may not be amiss to repeat what I must have said before—that to grow Orange trees well enough to produce fruit of superior quality to place upon the dessert-table there are a few essentials that cannot be dispensed with. It seems necessary to urge the following points, because one seldom sees the trees doing so well as they ought to do. In the first place peaty soil, such as imported trees are potted in, will not do. Good turfy loam, enriched with some stable-manure and bone-dust, is the best material to support the roots. In potting the compost should be pounded in rather firmly; the pots to be well drained; and as the trees may be two or three years—or, in the case of large specimens, even longer—in the same pots, some fibrous loam, free from dust, should be laid over the drainage. Cleanliness is next in importance. The Orange is often infested with scale, and mealy-bug will also get on to them. There is no better plan than to wash the trees with strong soft-soapy water, washing leaves and stems thoroughly. They may then be kept clean by thoroughly washing them with the syringe every day. Temperature is also of vital importance. Oranges will become yellow, the hue of ripeness, and they will grow to a large size in an ordinary greenhouse, but they will not be eatable. To have them of good flavour they must be grown in a stove temperature. Then the varieties must be selected; varieties usually imported from France will not answer. Tangierine, Maltese Blood, St. Michael's, and Plata, or Silver Orange, are the best. They should now be grown on in a high temperature, with a moist atmosphere; but if the fruit shows any sign of cracking, keep the trees rather dry at the roots.—F. DOUGLAS.—*Gardeners' Chronicle.*

[In consequence of the delay of the London Mail of August 4th through the breakdown of the Messageries steamer, we omit the usual London Price Current for Tropical Products this month.—ED.]

CINCHONA IN THE LOWCOUNTRY OF CEYLON.

The experiment in course of trial near Kalutara (reported by "W. L. F.") may be fraught with very important consequences. The leaves sent to us of ledgeriana, pubescens and condaminea, growing at so low an elevation as 200 feet above sea-level, shew healthy and luxuriant growth. Curiously enough, it is the red bark trees (succirubra) which fail at so low an elevation, instead of ledgeriana, the native habitat of which is 5,000 feet above sea-level. Accordingly, in first experiments it was tried at high elevations in Ceylon. Experience has shewn that it grows better in low warm sites, and *how low* it can be grown will depend on the quality of the bark of the trees which are now flourishing at 200 feet only of altitude. So with the "pubescens" and "condaminea" trees. We are not surprized to hear of a tendency to premature blossoming, as the same tendency is displayed at the other extreme of high altitude. In both cases, we suppose, it would be wise to deprive the plants of their blossoms? If, as we suppose, "pubescens" is a hybrid between succirubra and officinalis, it is a curious circumstance that the hybrid should succeed at a level too low for that parent which specially suits low altitudes. It seems as if the hybrid, like the tea plant, will grow from sea-level to 7,000 feet altitude. At the latter elevation in Ceylon hybrids are growing where officinalis died out, although we were taught, and the experiment on Dodabetta seemed to prove, that this was *the* species for high elevations. If what is called "condaminea" is a variety of officinalis, and not, as we suspect, a hybrid, then it is still more curious to find it so wonderfully adapted to changed conditions, not even shewing a disposition to premature flowering, as pubescens, "freely," and ledgeriana also do. There is another fact of very considerable interest and importance. The estate in Dolosbage whence the plants were brought to be "put out" at 200 feet above sea-level has an altitude of, at least, 2,500 feet. The plants, therefore, are flourishing at an elevation 2,300 feet lower than the nurseries in which they were reared. Unless the free flowering of the pubescens (healthy otherwise) is to be ascribed to the shock of this change of climate, no evil effects seem to have followed. But, as it is bark more or less copiously yielding alkaloids which is desiderated in cinchona cultivation, the great question now is as to the quality of the bark. We should think it is not too early even at present to take specimens of bark for analysis from some of the trees, and the process should be repeated (the results, we trust, being published) at intervals not longer than six months. If trees at so low an altitude can produce bark moderately rich in alkaloids, it is obvious that the whole enterprize of cinchona cultivation will be revolutionized.

REPORT ON CEYLON INDIARUBBER.

We take the following from correspondence printed in the *Gazette* by direction of the Governor:—

W. T. THISELTON DYER, Esq., C.M.G. to the COLONIAL OFFICE.
Royal Gardens, Kew, 30th June 1882.

Sir,—I am directed by Sir Joseph Hooker to inform you that Dr. Trimen, the Director of the Royal Botanic Garden, Peradeniya, has brought with him to this country a sample of the caoutchouc of the Ceara-rubber tree, (*Manihot Glaziovii*) of Ceylon production. It will be in your recollection that it was introduced into Ceylon in 1877 as part of an undertaking initiated by the Government of India, and carried out from Kew at its expense for the purpose of introducing the most important caoutchouc-yielding plants of South America into the tropics of the Old World. The Ceara-rubber plants went out to Ceylon in charge of Mr. Morris, the late Assistant Director of the Royal Botanic Garden, Peradeniya.

This sample is the first of bulk sufficient for experimental ipurposes, which has been yielded by he trees at Peradeniya. I am now to submit for your information copies of a correspondence with Messrs. S. W. Silver & Co. as to its commercial value.

I may remark that too great importance need not be attached to the difference between samples numbers 1 and 2, which is probably in great measure a mere accident. There seems no reason to doubt that the bulk of Ceara-rubber produced in Ceylon might be up to the standard of No. 1, the value of which Messrs. S. W. Silver & Co. estimate at from 2*s* 9*d* to 3*s* per lb.

I may add that Dr. Trimen states that the Para-rubber plants (*Hevea*) seeded last year for the first time, and that the (*Castilloa*) was in flower when he left the island. These circumstances are of the more interest as these species have proved difficult of propagation from cuttings in Ceylon.—I am, &c., W. T. THISELTON DYER, Assistant Director.

W. T. THISELTON DYER, Esq., C.M.G. to S. W. SILVER, Esq.
Royal Gardens, Kew, 17th June 1882.

Dear Sir,—It will be within your recollection that the plant (*Manihot Glaziovii*) which yields Ceara-rubber has been introduced into Ceylon at the expense of the Government of India. It is now thoroughly naturalized there, and is likely to become practically a weed. Dr. Trimen, the Director of the Royal Botanic Garden, Peradeniya, arrived in England from Ceylon on the 15th. He brought with him the accompanying samples of rubber from the Ceara plant, the first which has been produced in the island.

Sir Joseph Hooker would esteem it a favour if you could give him an estimate of the commercial value of the article as now sent you.

There are two samples, and you will observe that that labelled (2) is more glutinous and sticky than that labelled (1). A separate estimate of the value of each, supposing them to be sufficient for the purpose, would greatly oblige.

Sir Joseph Hooker ventures to trouble you in the matter, remembering the kind assistance which on other occasions you have rendered this establishment. He also feels, that, as an opinion on the results of the experiment will be anxiously anticipated in Ceylon, he cannot apply to a more authoritative source for an estimate which will be accepted with confidence.—I am, &c., W. T. THISELTON DYER.

The INDIA-RUBBER, GUTTA-PERCHA, and TELEGRAPH WORKS Co., Limited, to W. T. THISELTON DYER, Esq., C.M.G., Assistant Director, Royal Gardens, Kew.
Silvertown, Essex, London, E., 29th June, 1882

Sir,—Referring to your letter of the 17th June to Mr. S. W. Silver, enclosing two samples of Ceara-rubber, we have now the honor to enclose you our Chemist's report on same after careful examination. The present market value of No. 1 sample is from 2*s* 9*d* to 3*s* per lb. No. 2 sample we do not consider worth more than from 1*s*. to 1*s* 3*d* per lb.—We remain, &c., The India-rubber, Gutta-percha, and Telegraph Works Co., Limited,

J. W. BAILEY.

Report of Examination of two Samples of Rubber from S. W. SILVER, Esq., accompanying letter from W. T. THISELTON DYER, Esq., C.M.G., Assistant Director, Royal Gardens, Kew.

Description, &c.—Sample No. 1 has a dry and compact appearance, is free from extraneous impurities, and from its tolerably uniform condition has been collected with care. It agrees in all respects with Ceara-rubber of good and sound quality.

Sample No. 2 is soft and sticky, and is mixed with a considerable quantity of coarse sand. It is much darker than No. 1. It is very desirable that a sample of No. 2, collected without this admixture of sand, should be examined. Whether this sand is accidentally or intentionally mixed, its presence would be a serious drawback to its use. For the better class of rubber manufactures it would be totally unsuited.

In Manufacture, &c.—Sample No. 1, when washed and dried, gives a loss of 8 per cent. This loss is much less than is met with in Ceara-rubber of the finest quality, and may probably be accounted for by the small bulk, and the facilities offered by time, mode of packing and transit, to the escape of the natural moisture of the product. Water removes a considerable quantity of mucilaginous and feculent matter and salts—the natural impurities of the rubber—and leaves it quite white and almost pure. Alcohol extracts but a slight amount of resinous and oxidation products. On incineration it yields 4·13 per cent mineral ash, which agrees, in its chemical composition, very closely with the ash obtained from Ceara-rubber, the ash from which amounts to 4 or 5 per cent. This sample (No. 1) vulcanizes perfectly when mixed with the suitable proportion of sulphur and heated.

Sample No. 2, when washed and dried, gives a loss of 62 (sixty-two) per cent. The sand renders it extremely difficult to wash, unless warm water is used, which increases its stickiness on drying. Water removes much less mucilaginous matter than from No. 1. Alcohol removes, even on long digestion, only a slight quantity of soluble matter. On digestion in alcohol it does not become harder or less sticky. This shows that its stickiness is not due to an oxidized state of the rubber, nor to the presence of resins, and would create an opinion that some other product has been added The chemical analys; is of the mineral ash in such cases is of great assistance the quantity of foreign mineral matter in sample No. 2 renders the analysis of the ash in the present case quite unreliable. It yields 27·53 per cent ash before washing, and 6·42 per cent ash when washed and dried. Sample No. 1, when washed and dried, yields 2·9 per cent ash, insoluble salts contained in the juice of the plant. When mixed with the suitable quantity of sulphur and heated, sample No. 2 vulcanizes, although not so satisfactorily as No. 1.—THOS. T. P. BRUCE WARREN, Analytical Chemist to the Indiarubber, Gutta-percha and Telegraph Company.

Silvertown, 29th June 1882.

CINCHONA BARK IN LONDON.

(From a Correspondent.)

The great variety of cinchona bark from Ceylon was the chief characteristic of the public auction on 18th July. Cinchona of every class of preparation, of succirubra, hybrid, and officinalis, was offered for sale, which gave valuers from appearance every opportunity of increasing their knowledge. Some classes were in more demand than others, perhaps owing to a great scarcity of cinchonidine prevailing. For anything in the shape of red quill, no matter whether uneven, unassorted, mixed, or thinnish, the prices given were higher than usual. Renewed red and renewed crown shavings sold very well; some of the latter from Upper Cranley realized as much as 6s 10d per lb. It would be interesting to know the details of that lot, such as age of trees, age of renewed bark, and whether the bark was procured from a second or a third shaving. 5s 1d per lb. was paid for renewed red shavings (well gnarled) from one of the Messrs. Campbell's Lindula estates. Some shavings from two year old officinalis trees sold for 2s per lb. Other features in the sale were hybrid shavings (the first offered perhaps) realizing from 2s 3d to 3s per lb., succirubra stump and root 2s, officinalis stump and root 3s 8d. Some 3 foot quill from New Brunswick brought 4s 5d per lb. There were as many as nine sales, and in all but one Ceylon bark was offered. There is a fall in the value both of good succirubra spoke-shavings and stem chips to 2s 6d. According to yesterday's sales detailed values are as follows approximately :—

Officinalis.				*Succirubra.*			
Twigs ...	0s	9d to 1s	7d	Twigs ...	0s	5d to 1s	4d
Chips ...	2s	0d to 4s	1d	Chips ..	2s	0d to 2s	6d
Root ...	2s	0d to 6s	7d	Root ...	1s	2d to 2s	4d
Stump ...	—	3s	8d	Stump...	—	2s	
Spoke .. shavings	2s	0d to 3s	10d	Spoke .. shavings	1s	6d to 2s	6d
Quill 2nd quality	2s	8d to 3s	6d	Quill 2nd quality	1s	10d to 2s	8d
,, 1st ,,	3s	8d to 6s	0d	,, 1st ,,	2s	10d to 5s	0d
Renewed	4s	3d to 6s	10d	Renewed	2s	6d to 5s	1d
Dust ...	0s	1d to 1s	7d	Dust ...			4d
Bits (a) ...	0s	0d to 1s	9d	Bits		1s	5d
Pieces (b)	1s	6d to 2s	0d	Pieces ...	1s	8d to 1s	10d
Hybrid quill				3s			
Hybrid stem chips...				1s	10d		
Hybrid shavings ..				2s	3d to 3s.		

J. H.

CONVERSION OF NITROGEN IN THE SOIL INTO NITRATES AND THE LOSS OF NITRATES AND DRAINAGE.

As the editor of the *Field* said in answer to his correspondent "Agricola," the loss of nitrates now is not greater than it was before Lawes experimented and Warington lectured, but we suppose a good many of our readers will share the feelings with which the revelations made have inspired us and others: especially our correspondent "X.," from whom a second communication appears today. What with Mr. Hughes' tremendous calculations of our loss of soil by wash, and now the statements as to the tendency of nitrogen to assume the form of nitrates, merely to be in large proportion lost in drainage, the case of agriculturists, tropical agriculturists especially, seems a hard one. We were led to believe that earth was the great filter and disinfectant provided by nature, with the power of assimilating all offensive substances, rendering them not merely harmless but beneficent, only letting the pure fluid flow away. But now we are told that the earth teems with *bacteria*, the most formidable agents of disease. Those low forms of organisms are also, Mr. Warington tells us, the agents which change nitrogen into nitrates, by a species of action which, for our comfort, we are told, is analogous to the action of the vinegar plant. If the process of nitrification takes place at a low temperature, but is wonderfully accelerated by summer heat, in England, how much more rapid must the process be under our tropical sun and how much greater the waste from our tropic rains?! Even in England, according to Mr. Warington, in growing a crop of wheat, the loss of nitrates in drainage was equivalent to that used in the production of the crop. The only comfort is that in certain subsoils the nitrates go far down and can, of course be again found, say in Ceylon by the deep roots of the tea plant. Our old idea of the retentive powers of the soil holds good it seems for superphosphate, but nitrate of soda is at the mercy of the weather! The value of bare fallowing, it appears, depends on the seasons. If these are mild, nitrates become superabundant: if the weather is wet, as has for years now been the case in England, the nitrates are washed away. Economical farming, it is laid down, very much depends on the economizing of the nitrates, and in wet seasons the only sufficient means of preserving the nitrates is to put in a crop which will absorb them. That is easily enough done in England but what are we to do on our coffee, cocoa tea and cinchona plantations, close to the equator? If *ageratum* or "white weed" was not possessed of such an inveterate tendency to seeding when scarcely above ground, we might be able to kill two birds with one stone

(a) Better than twigs.
(b) Not so good as stem chips.

by utilizing it. It contains all the elements of coffee So do the lupins, which Liebig recommended should be grown amongst our coffee and turned down into the soil as "green manure." All the pulses are great absorbers of nitrogen, and the rape plant has been specially recommended to our notice. Most opportunely we find an article on the Indian culture of this plant in the *Indian Agriculturist*, which we shall subsequently notice. We should feel more about the excessive wet of the monsoon just closing, but that, as far as the application of manure to the soil is concerned, there were so few nitrates to be washed away. As matters stand, experienced planters hope much from a reaction to hot, droughty weather. As ploughing on our plantations seems out of the question, the problem to be solved seems to be :—Can we by the hoe or fork so prepare our soil as to enable it to bear a crop of mustard or of rape so thick as to choke all ordinary weeds, the sown crop itself being hoed down into the soil before the flowering stage—during that stage —or when the seed vessels are quite green? We suppose the plants will have absorbed the maximum of nitrogen in this last stage? In face of the opinion that the whole of the ammonium salts applied to land might be nitrified and lost in forty-eight hours from the time of application it is comforting to learn that the silicates in the soil (and our plantation soils consist mainly of silica) have the power of absorbing ammonia with which they come in contact. Our loss, therefore, in this direction, may not be so great as we are apt to fear, in view of doctrines which led the correspondent of the *Field* to write that they were "rather calculated to deter everybody from undertaking the task of exciting in the soil a fertility which, in addition to the labour and expense required to produce it, is stated to be extremely liable at any time to be washed out of the soil, into the drains." The answer of the editor is that the knowledge of the truth will not aggravate the evil, and that the loss of nitrates "may be prevented by a crop." In our case when coffee, cinchona, tea cocoa, &c., are full grown, we have standing crops, the feeding rootlets of which ought to absorb a very large proportion of the nitrates. It is the case of young clearings, especially in the hot "low-country," which is calculated to excite anxiety. A correspondent of our own, "X.," has impressed on the planting community the gravity of the subject and contended that altogether *one million sterling per annum* was lost through causes more or less remediable! As this correspondent is compelled to concede, planters will not be ready to admit that they have erred in being so careful to take weeds out of and put drains into their lands. If on our steep hill sides an experiment in terracing, similar in principle to that which the natives apply to their rice fields can be carried out at a moderate cost, we shall be glad to have the details. Where we have seen terracing for tea, on the rich deep soil of the Eastern Himalayas (Darjeeling) and in the decomposed lavas of Java, the process was facilitated by two qualities of the soil: the earth was easily worked, and the subsoil turned up was in no respect inferior to the surface soil. In fact the distinction of soil and subsoil did not exist. Of how few of our soils in Ceylon can this be said? In our own experience a small experiment in terracing for fine quality cinchonas was very expensive, and the result by no means so beneficial as we hoped. One experiment is not conclusive, however. On a considerable proportion of our plantation land, terracing is simply inadmissible, the inclines being too steep even for stirring with the fork. Crops of which any part is to be taken away from the soil, such as beetroot, are open to grave objections. Even kurakan and sweet potato growing amongst coconut palms is exhaustive of the humus of the soil. But either mustard (said to be an antidote to wireworm) or rape, which can, with all its absorbed nitrogen, be turned down into the soil, seems to be in quite a different category. Experiments in this direction ought, we think, to be tried. The question asked by our correspondent "X.," too. whether the presence in the soil of bacteria necessary to the formation of nitrates and their passing into water may not account for the existence of fever, is worthy of attention. We do not know if the idea has been previously started, but it seems deserving of being followed up. For no one has ever yet really laid his hand on the origin of jungle fever. "Malaria" is, after all, a very indefinite term.

But to the practical point of rape as a nitrogen-absorbing plant, to be grown amongst coffee, cinchona, tea, &c., on plantations. From the article in the *Indian Agriculturist* we find that, in class, order, and scientific name, rape is closely allied to mustard, and that, like that pungent plant, it is in India largely cultivated for the sake of its oil. But some of our readers may be surprised to learn that this plant, with its "robust, succulent tap-root," is not only a member of the cabbage tribe, but is a type from which, by cultivation, have originated the Swedish and Teltower turnips. Both rape and mustard are annual plants, and the writer in the article we are noticing states :—

The short duration of its life, the almost no cultivation given, without irrigation and manure, the comparative heavy yield—2-5 maunds an acre, and the high market the seed commands—12-16 seers to the rupee, prompt many cultivators to grow the rape plant as extensively as their means and suitableness of the soil and climate will admit.

Of course it would not be cultivated on estates for the sake of its seed. From the fact mentioned, that the plant is largely grown in parts of Oudh bordering the Himalayas, the probability is it would flourish in our hill country. Rape oil as an edible as well as a lamp oil enters very largely into Indian cookery. From a long list of savoury preparations described, we copy the first :—

Pooree or *toochee*. This is made of coarse wheaten flour (H. *ātā*) made into dough and balls, pressed and shaped like biscuits by means of H. *belun* and *chowkee* (wooden roller and circular piece of wood or stone slab); and fried in boiling oil (H. *et* B. *tel*) in a H. *karhai*, B. *korae* (circular iron or brass pan). This is poor man's *pooree*. The rich, however, substituting *moida* B., *maida* H., for *ata* and ghee, for oil. Among the Hindus, *pooree* is considered a dainty food, and is the favourite viand on all high occasions; in festivities, marriages, etc. It is termed *paka khana* H., and *chapatis* H., and *bhat* H, *kacha khana*.

We quote again :—

The residue oilcake is sold by the name of *sarson kakhali* H., *shorshaye khol* B., which is used as food for the live-stock in the winter season. It is not administered in the summer, being considered heating. This oil-cake sells much cheaper than that of the linseed, and is therefore available as valuable manure—rich in most elements required by plant life; especially in phosphoric acid, potash, magnesia, lime, and silica (*vide* analysis.)

The pericarp leaves and stem are good sheep-fodder; but is rarely given in India. Indian goats and animals of the bovine species do not appear to have much predilection for them; and they are available as very good manure (*vide* analysis).

Lastly, the fresh flowers and peduncles, tied in a thin cloth, boiled and mixed with a little mustard oil, salt, and a pinch of powdered black pepper, are eaten in Bengal by the name of *shorshaiere phoolere*, bhorta B. The tender top, nipped, and fried in mustard oil with admixture of chillies and salt. Eaten by both Bengalees and Hin-

dustanis, under the name of *shorosheyre shág* B., *láhee ká ság* H.

Under the head "climate" we are told :—

This plant is an annual, and prefers a temperate climate. Being hardy it will succeed even in the frigid zone (Baron Mueller). Frost does no injury if irrigated, nor any quantity of rain : westerly winds of Upper India favours the healthy growth, and long continued cloudy weather favours *abbis*, a small fly (H. *máhoo*), which attacks this and all other plants of N. O. *cruciferæ*, more or less ; and within a few days, nay, a few hours, generates in myriads, feeds on all parts of the plant, especially the flowers, pods and tender leaves, and ultimately destroys the crop wholesale. There is no means of extirpation of this formidable pest.

So that we can grow nothing which has not its fungoid or insect enemies, and it might be a serious question whether in growing rape we might not be introducing a fresh insect foe to our regular culture. To quote again :—

TIME OF SOWING.—No time should be lost to sow the seed just after the thorough cessation of the rains—middle to end of September ; and, if possible, a fortnight earlier. Later sowing exposes the crop to attacks from the *abbis*.

GEOGRAPHICAL DISTRIBUTION.—A native of various parts of Europe (Baron Mueller): also indigenous to Northern India ; ascending as high as 15,000 feet in the Himalayan mountains (Sir W. Jackson Hooker).

SOIL.—The rape, like all other plants of the cabbage tribe, requires a very rich and heavy soil. *Argillaceous soil* of the *calcareous order*, and of the species not too poor in sand and *humus*. Composition of soil :—

Clay...	...	70	parts.
Lime	...	5	,,
Humus	...	4	,,
Sand	...	21	,,
		100	,,

CHEMISTRY OF THE RAPE PLANT.—The produce of one acre—seed, pericarp, leaves, and stem (vide *heading yield*) has :—

Seed...	265·146 lb.	of *inorganic* matter
Do ...	5,844·541 ,,	,, *organic* ,,
	6,109·687 ,,	
Pericarp, leaves, and stem..	673 591 ,,	of inorganic matter.
Do. ...	14,600·595 ,,	,, organic ,,
	15,274 186 lb.	

Chemical analyses of the *inorganic* portions of the above :—

	Seed.	Leaves, stem, and pericarp.
	lb.	lb.
Potash	43·483	113·836
Soda	1.325	72·074
Chloride of sodium	2·651	16·166
Lime	22·007	142·801
Magnesia	23·333	20·207
Oxide of iron	4 772	8·756
Phosphoric acid	85·377	38·394
Sulphuric acid	14·317	26·270
Carbonic acid	14·848	155·599
Silica	53 029	79·483
Total	265·142	673·586

From the above table, the kinds and quantities of elementary substances required are redundant, which the soil on which the plant is to be raised must contain or must be supplied as manure, otherwise the plant will not grow, flourish, and yield according to the expectations of the cultivator.

More places of decimals have not been given, as the difference of a grain or so in each elementary substance in an acre, is immaterial for the application of manure. Where the decimal figures are less than ·500, half a pound, and more than ·500, one pound, should be computed for manure.

Rape plant belongs to the *lime order*.—(Liebig).

It will be seen that rape, allowed to seed, which we do not contemplate, takes from the soil large quantities of potash, lime, and phosphoric acid. To allow the plant to ripen its seed, therefore, would seem to be, for the purpose we have in view, a fatal mistake. It ought to be buried in the soil when green, and we should think caustic lime ought to be added to hasten decomposition and prevent the formation of fungi. About manure for rape, ploughing and water channels for irrigation, we need not quote ; nor need we cultivate in "ridges." But as the Indian cultivation is for ridges with plants a foot apart, we should probably, for thick, broadcast sowing use double, or treble the Indian allowance of 1 seer or as we say in Ceylon measure ($\frac{1}{32}$ part of a bushel) of seed per acre. Care should be taken to obtain clean, well sifted seed. Hand-sowing will suffice for estate experiments, but for extensive culture of this and other plants the Indian writer recommends the "beet-sowing machine" recently invented in France. Cultivated for seed the maximum yield obtained from rape by the writer of the article was :—

Seed	6,109	lb.
Pericarp	3,054	,,
Leaves and stem	12,219	,,
Total ...	21,382	lb.

The seed being thus somewhat under one-third of the whole. Sown thickly to be turned into the soil before the appearance of flowers, we should think 20,000 lb per acre could be calculated on. Lime added at the rate of at least 5 cwt. per acre would we should think be beneficial.

It is possible that from its pungency, mustard may be preferable, as inimical to insects instead of invitiug their attacks. We do not suppose there need be any difference in the mode of cultivation : sown broadcast over forked soil. As in the case of rape, we ought probably to obtain seed of the Indian variety, which is very largely grown on the opposite continent for lighting oil. The Indian mustard is distinguished as *Sinapis ramosa*. The "hill mustard," which is said to be a different genus, *Bunias*, might suit our higher altitudes. Seed of each could be obtained for experiments. Dr. Trimen could obtain seed through Dr. King of Howrah or Mr. Buck of the Indian Agricultural Department.

NITRIFICATION OF AMMONIA AND LOSS OF NITRATES: PIGS ON COFFEE ESTATES.

(To the Editor of the Ceylon Observer.)

Udagama, August 18.

DEAR SIR.—I must thank you for affording your space to so long a letter as my last in your issue of the 5th instant, and will not further ask to occupy it now in attempting to correct a slight mixing up of stops and capital letters—attributable I am free to admit to faulty writing—as my meaning under all important headings stands unaltered. But I would wish to add that I had overlooked subsequent letters in the *Field* commenting on Mr. Warington's lectures, and that appear in your August number of the *Tropical Agriculturist*—though I do not see that they afford material to do more than perhaps somewhat modify my conclusion. It is true that Messrs. Lawes and Gilbert in their "practical conclusions" tell us "the nitrogenous compounds of the soil itself

are very slowly converted into nitric acid, but the soil yields up a certain quantity every year," but I take it this refers to *old* or *subsoils*, and cannot apply to the fresh surface soil of a new clearing—virtually nothing more or less than a top dressing of manure in the form of organic matter; though albeit a manure less rapidly susceptible to the formation of nitrates; and it is in some sense satisfactory to know that the same rule to some and a greater extent than I fancied, applies to rape and I suppose, therefore, to other descriptions of poonac. But on the other hand are not the hopes thus extended completely cancelled, by the ruinous activity, Mr. Warington's remarks would lead us to suppose, a climate such as ours exerts in the creation of nitrates? And this view is supported by Mr. Lawes:—"Under favourable conditions of temperature and moisture, nitric acid is produced with rapidity." (See page 114 *T. A.*) Further on we are told "the nitrifying plant cannot carry on its work unless it is furnished with alkaline substances," and it is *suggested* that phosphates may also be necessary. In all our soils alkalies of some sort I fancy abound; though should it be that phosphates are also required it perhaps may be inferred that poor soils, on being deprived of vegetation, lose their nitrogen less rapidly than rich ones. Also, that the application of phosphoric acid, in the form of bonedust or otherwise, in excess, may have a tendency to exhaust the existing nitrogen. As regards conserving the latter: how would it do to eat-off any green crop it might be decided to grow amongst the coffee &c.? But I would say with pigs in preference to *sheep*—for I do not remember pigs loose about the lines ever doing any material damage to old coffee, and in crop time they could be housed; and not only do they give a very rich manure, but I am not sure that they would not be a complete antidote to grub. With other vegetable matter besides the coffee roots to feed on the latter would not probably confine their attention to these only: and anyhow I believe the pigs would ruthlessly and quickly grub out every one of them. And the harm thus occasionally done to the coffee would I feel sure prove but a *minor* evil! No old tree would be, *but partially*, uprooted—and the cause removed—to be set straight again, and a little fresh earth stamped round would speedily rectify all semblance of injury. Grubbing about with their snouts, the manure and rotting vegetable matter too would be worked into the soil. This is an idea that I know will be laughed at—and welcome! All I ask is accompany the laugh with a substantial reason. If none are forthcoming an acre, to be surrounded by movable hurdles as at home, thus treated would not be a ruinous experiment. X.

THE LOSS OF NITRATES QUESTION.

Sir,—A letter signed "X.," appearing in your issue of 5th instant, has hitherto attracted no attention. It is based upon a lecture by Mr. Warington, reproduced in the July *Tropical Agriculturist*. I am indebted to "X." for drawing my attention to this very concise, clear and pithy paper, from which I gather that nitrification or the formation of nitrates, which constitute the most suitable form in which nitrogen is absorbed by plants, takes place chiefly on the surface soil, and that these from their great solubility are readily washed through the soil, unless there is plant life present to take them up and use them. I learn further that nitrates are as readily and regularly produced as they are easily lost, and that the loss is diminished by the presence of a crop. Mr. Warington is lecturing specially on the loss of nitrates in wheat cultivation, and shows that, though a bare fallow increases the nitrates, they are better preserved under a crop rotation. It appears then that, if wheat—a great absorber of nitrates—were perennial, there would be no loss of nitrates because the wheat would always be absorbing them as they were formed.* "X." endeavours to apply the facts and logical conclusions of Mr. Warington in reference to wheat to the perennials coffee and tea. Now the preservation of nitrates is of vast importance to the wheat-grower, because he knows that wheat is a greedy devourer of this compound, but to the tea and coffee planter the loss of nitrates is of no importance, until he *knows* that there is a deficiency in the soil. What we do know is that we are living in a country where nitrates are rapidly and continuously made owing to the higher atmospheric temperature. "X." *assumes* that we are suffering from loss of nitrogen, and that this is accelerated by close draining. If this, which is not proved, be the case, it is surely better that some of the nitrates should be washed deeper into the soil and some lost in the drains, than that the surface soil itself should be carried with ever-increasing force and rapidity down the whole face of a long hill. If "X." would first prove that coffee or tea or any of our new products were suffering from loss of nitrogen, there would be some cause for his letter, and, perhaps, some sense in his remarks about mustard and beet crops. He should not, however, say that Mr. Warington advises these, as that gentleman is speaking specially of annual crops. "X.," to suit his argument, assumes twice the loss of nitrates here as compared with England; he might with more certainty assume the production to be four times as large. Mr. Warington gives us facts based on actual experiment, "X." gives us theories not based on any thing. Mr. Warington deprecates being considered a practical farmer, "X." says nothing to lead one to suppose that he is practical either as planter or chemist. He speaks, however, as one in authority What a boon he might confer on the planting community, if he were to supplement Mr. Bosanquet's useful experiments by analyses of the drainage water and soil. Y.

[These are just what we want and ought to have, for surely this writer is not serious in stating that the loss of nitrates is "of no importance" to the coffee and tea planter. In the article in another column, written before the receipt of this letter, we pointed out that, on the older estates, the feeding rootlets of coffee, tea, &c., ought to absorb the nitrates. It is on new clearings, especially in the lowcountry, that green crops, such as mustard or rape might prove useful.—Ed.]

THE MADRAS SCHOOL OF AGRICULTURE.

The *Indian Mirror*:—It is undeniable that the Madras School of Agriculture is engaged in doing most useful work. Through the experiments it is carrying on with such general success, it is gradually paving the way to the introduction of a thorough reform in the present methods and implements of Indian agriculture. It is doing what is better still—it is raising a body of men who can at all times carry out and perpetuate that reform which is so necessary in a country so purely agricultural. The rate at which population is increasing in every part of the Empire, is fast outstripping the productive powers of a soil, rich it is true, with tropical fertility, but gradually exhausted by a reckless system of cultivation. Doubtless, much new land remains to be broken up. But it seems to us that such new land may be held in reserve to fall back upon hereafter, while such old

* Mr. Warington expressly adduces an instance where as great a quantity was lost in drainage as was absorbed by the wheat in forming a crop.—Ed.

land as has already been brought under the plough, and drained of its fecundity, should be reinvigorated for productive purposes by those artificial resources which modern science has placed within our reach. It should be cheaper to renew an exhausted soil than to break up virgin soil, except where it lies in the vicinity of cultivation; for the poverty of the agricultural classes generally would prevent them from shifting their homesteads to new and more distant sites, even if their prejudices allowed them to remove from localities to which they are already bound by many close associations With agriculture in so backward a state as it is in this country, it is surprising that our large and wealthy Zemindars do not endeavour to secure the services of these passed students to introduce agricultural improvements on their estates. But, unfortunately for this country, our Zemindars are optimists, and think that the present condition of things is the best condition possible, and needs no change. While ready to waste unconsidered sums of money in hopes of gaining titles, they will not spend a rupee in contributing to the advancement of their countrymen and the welfare of their country. Rather than avail themselves of the services of the young men, trained in agricultural science and capable of benefiting themselves, their tenantry and their estates, they prefer the traditional *gomashta* who knows no better than his fathers, and likes things to run on in their old groove. It is very much to be regretted that in Bengal, the most agricultural Province in a purely agricultural country, a similar school was not established. If Sir George Campbell had remained at the head of the Government of Bengal for the full term of his office, we have no doubt but that he would have seen his way to the foundation of such an institution. But unfortunately for this Province, neither the Government nor the Zemindars take that interest in agriculture which is its staple industry and its surest source of increasing wealth. It is gratifying to observe that Maharajah Holkar with his ususal intelligence, has laid down the germs of an Agricultural Department for his State in the State Farm which is working with some success under a superintendent, trained in the Madras Agricultural College. We should be glad to see His Highness' example followed by other Feudatory Princes.—*Madras Mail.*

LEDGERIANA CINCHONA COMPANY.

London, 18th July.

When last writing, my letter mentioned that the prospectus of the Ledgeriana Cinchona Company had been printed. A few extracts from it may be of interest to the many in Ceylon who desire to see the introduction into your colony of fresh capital. No later information has reached me since last writing of further progress with this undertaking, the objects of which are stated to be :—"To acquire by purchase, or by lease for long periods, freehold lands in Ceylon, Jamaica, and in Java : and to plant and cultivate upon them trees of the different varieties of cinchona. To acquire by purchase, or by lease for long periods, freehold lands in the above-mentioned islands, upon which cinchona trees have already been planted." The prospectus then proceeds to discuss the cost of producing cinchona bark, premising "that by the time the cinchona bark, which the Company is now about to grow, is marketable, the prices will still be considerably in excess of what their bark has cost them to place in the market." The estimated expenditure for bringing an acre of ledgeriana into the sixth year of growth in Ceylon is £80, land being estimated at £5 per acre. The cost for succirubra is estimated at £52. Fifteen hundred Ledgeriana trees are rated to the acre, and the return is averaged at 1 lb. of bark each, the total return of 1,500 lb. being priced at 5s per lb., or £375 for the whole. The succirubra is presumed to give 1½ lb. of bark per tree, equal to 2,250 lb., expected to sell for 1s 6d per lb., or £168 in all. These figures are based on the assumption that, at the end of the sixth year, the trees are completely uprooted, but the prospectus then proceeds to consider the results of gradual harvesting by "shaving." "Treated in this way, the return from an acre of Ledgeriana would be, during the three years from six to nine (inclusive) of the plantation's history, a total of £125, or about £40 per annum, arrived at thus :—500 trees (Ledgeriana) giving ⅓ lb. each of bark, *i. e.* 166 lb. at 5s (about—£40.)" After that period the renewed bark will, the promoters write, fetch higher prices. Then, dealing with succirubra similarly treated, the prospectus under review continues:—"An acre of succirubra in this way would in the first three years from the sixth year of the plantation's life, give from ⅓rd of the trees, 500 lb. of bark at 1s 6d to £37 ; in addition to 500 lb. of bark from another ⅓rd of the trees, which must be uprooted gradually, as succirubra trees are of too vigorous a nature to allow more than one thousand trees to cover the ground after the sixth year = to £37 more, or a total of £74." This would be equal to about £25 per annum. The history of cinchona planting in Ceylon is then reviewed, and the failure of the delicate officinalis kind referred to. It is thought desirable that growing estates, heavily in bearing, or in full bearing, should be purchased to ensure immediate return on capital, and the embarrassed position of many Ceylon planters is advanced as encouraging the hope that many properties could now be purchased on advantageous terms ; it being believed that, when trees are from 2 to 3 years old, an estate could be purchased for an average of about 1s per tree. A second part of the prospectus, or an addendum to it, is devoted to the consideration of the probable future prices of cinchona bark. Into this space forbids my entering, and the subject too is rather of a speculative character, and does not possess the interest of the figures as to cost of production, which have been above given, and which will doubtless evoke criticism, either for or against them, from experts among you. As the Company is not yet matured, it is not open to me to send you the copy of the first prospectus, but I am permitted to make extracts of the foregoing figures.—London *Cor.*

UVA COFFEE COMPANY.

The following are the principal statements of the Uva Coffee Company's report :—

The season produced the smallest crop yet gathered from the Company's estates ; 4,042 cwt of coffee, exclusive of inferior pickings, sold in the island. The sales in Ceylon and London aggregated £14,478 1s 5d only, owing to the fall in the value of coffee during the year, but for which a small bargain of profit would have been shown. Cinchona bark stripped from the old trees on the estates, and weighing 48 cwt, has realized to £548 11s 2d.

The net result of the year's operations is a loss of £1,007 2s, which has to be set against the balance of profit carried forward last year, £8,084 16s, leaving £7,077 14s to credit of revenue. Out of this the directors declared and paid in January last a dividend of 2½ per cent, or £2,500, so that there remains an undivided balance of £4,577 14s as shown in the statement. Under more favorable circumstances they would, as they hoped to do, recommend a further distribution at the present time ; but looking to the serious fall experienced in the coffee market during the current year, and to the excessive stocks held in Europe, they are unwilling for her to entrench upon the funds at their disposal, until the realisation of the crop

1881-82 now arriving is more assured. They, therefore, consider it prudent to defer any further payment of dividend until January, 1883, when they will be better able to estimate the result of the current season, and to form an opinion of the prospects for 1882-83.

The crop of 1881-82, now in course of shipment, will probably not amount to much more than 5,500 cwt. Expenditure is confined to necessary outlay upon the upkeep of the estate, and to the extension of improved appliances for the distribution of manure. The falling-off in the productiveness of the estates during two consecutive seasons may without doubt be attributed in a large measure to leaf-disease, the spread of which has unfortunately been assisted, while the forming of fruit has been prevented, by unusual atmospheric conditions. Latest reports, however, confirm the directors in their belief that the disease has not permanently injured the trees, and hopes are entertained that it will in course of time wear itself out, as has been the case with other pests.

Returns from cinchona bark will during the next few years gradually increase as a separate source of income. There are already planted on the properties about a million cinchona trees of various kinds, and the nurseries contain a large number for future planting.

Cocoa is growing successfully on Rockhill, and is to be also planted on a small portion of Ballagalla.

It is to be regretted that the result of the year's operations is a loss. The balance of last year leaves a not inconsiderable sum in hand, but it will no doubt be thought a wise act of the directors not to trench upon it by payment of a further dividend at present.

IMPORT DUTIES ON CEYLON PRODUCTS IN THE AUSTRALASIAN COLONIES.

The *Australasian Trade Review* is as severe as the London *Times* on the conflicting and hostile tariffs of the seven colonies, including New Zealand, which go to make up the Australasian group. To quote :—

The principles underlying colonial taxation are inscrutable. No two colonies even employ the same nomenclature as regards denominations of weights or measures. An article may be taxed at per lb. in one colony, at per ton in another, and under the *ad valorem* system in a third. In one colony the only aim seems to be to raise money by any clumsy method, and in a second to arbitrarily select a number of industries and tax the community to support them. How necessary it is that some common method of taxation should be adopted is evident from the table of Australasian import duties comparatively arranged, which we print in another part of this issue. That people of the same race, with like interests and aims, with, we believe, the prospect of ultimate union before them, should in so grave a matter as commercial intercourse vex and harass one another in the barbarous fashion revealed by that table, would be incredible if the fact were not patent. That the public attention is being aroused on the subject is not to be wondered at, and it is to be hoped that an overpowering public outcry will be raised for an intercolonial Customs union.

From the table referred to we gather that *coffee* in its raw state is charged 3d per lb. in Victoria, New South Wales South Australia, Tasmania and New Zealand. In Queensland the charge is 4d, and in Western Australia only 2d. There is no distinction in the case of the roasted article in Victoria, N. S. Wales and Western Australia; but in Queensland the charge is 6d. in S. Australia and Tasmania 4d, and in New Zealand 5d. In connection with coffee we may say that the duty on *chicory* is 3d per lb. in Victoria, N. S. Wales, and New Zealand; 4d in Queensland, S. Australasia and Tasmania; and 2d in Western Australia. *Chocolate* is charged 3d per lb. in Victoria, N. S. Wales, S. Australia, Tasmania and N. Zealand; 4d in Queensland; and 2d in W. Australia. *Cocoa* beans are free in Victoria; 3d per lb. in N. S. Wales, S. Australia Tasmania and N. Zealand; in Queensland and W. Australia 2d. "Prepared" beans are 3d in Victoria, N. S. Wales, S. Australia, Tasmania and New Zealand; 4d in Queensland; and 2d in W. Australia. Coconut oil is not separately shewn in the table. *Spices*, including, of course, cinnamon, are charged 2d per lb. in Victoria, when ground; unground free. The charge in N. S. Wales Queensland, and S. Australia is 2d; in W. Australia and N. Zealand 3d; and in Tasmania 4d. The duties on *tea* are 3d per lb in Victoria, N. S. Wales and S. Australia; 6d (£2 per maund) in Queensland and Tasmania*; and 4d in W. Australia and New Zealand. As our readers are aware, the duty on tea in Victoria, which Sir Bryan O'Loghlen proposed to abolish, is now to be retained. The average value of the China tea sent to Australia is scarcely one shilling per lb., but Indian tea brings the whole up to about the shilling in bond. The duty of 3d per lb. therefore is 25 per cent on the value; the 4d duty 33⅓ per cent; while the 6d duty in England and the Australian colonies which levy it is 50 per cent of the value. This is a heavy impost, but if a general war follows the present outbreak in Egypt we fear an enhancement rather than a reduction of the English duty may be anticipated. The present too is not a time for the Australian colonies largely to reduce any taxes, but it is to be hoped they will at no distant date confederate for Customs purposes as well as self-defence.

ARTIFICIAL QUININE.

(*To the Editor, "Madras Mail."*)

SIR,—A few weeks ago the English papers mentioned the discovery of artificial Quinine by a Chemist in Paris. We wrote to our correspondents in London on the subject, and have much pleasure in enclosing a copy of their reply, which will be of interest to Planters in India and Ceylon.

Madras, 9th August. CROYSDALE AND Co.

Messrs. Croysdale, & Co., Madras.

DEAR SIR,—. . . The Synthetic manufacture of Quinine has always been the dream of Chemists, and is considered possible by some of the Quinine manufacturers, but, as yet, has never been accomplished. You will observe that even M. Mannene, does not consider his process perfect, and we fancy that a less interested judge might find it impracticable, and even should it be accomplished, there remain two things to be considered.

1st. Expense.

2nd. Would it have the same effect on the human frame? For, it is a well-known fact that articles manufactured synthetically sometimes have different effects from those of the article manufactured naturally, although the chemists' formula may be similar. This is a most important point, for it is not here a question of a dye, like Indigo, but of the most important chemical, used in cases where the issues of life and death, humanly speaking, hang on its quality.

Again, should the synthetic article be really identical in results with natural article, then, prejudice will step in, and we wish the Planters of Cinchona could know what a stubborn obstacle this is to the introduction of anything new. People will not experiment, medical practitioners dare not. The experience we had introducing the Neilgherry Cinchona, which, after all, produced the same article as the South American bark did, per made us that any change must be a very gradual process, and any new article must take a long time to work its way into practical use.

This Synthetic Quinine is no new idea, we have been threatened with it for many years, and, as a trade, we ignore it, and think the Neilgherry Planters of Cinchona can afford to do the same, if for no other reason than the following :—

Should this invention be what it claims to be, and should it, after much time spent in overcoming prejudice, enter into the market as a reality, the almost certain effect would be to drive the present Quinine manufacturers into the necessity of forcing on the public the valuable qualities of the other Alkaloids contained in the bark, some of them really superior in effects, in some cases to Quinine itself, which Alkaloids are at present neglected. We should then see the difference in price between Quinine and the other Alkaloids almost disappear, and the manufacturers would be able to produce Quinine at an infinitely lower cost, whilst still being able to pay remmerative prices for the bark in consequence of the increased value of what are now considered bye products. When the Neilgherry Cinchona Planters consider that their succedaneas, so rich in Alkaloids, would thus lose on the one hand from lower prices of Quinine, and gain on the other from higher proportionate prices of the

* Proposed to be reduced to 4d from 1st January, 1882.

other Alkaloids, we think we may advise them to let the future take care of itself, and go quietly on trying to produce a really good rich bark, without misgivings as to a fair return. —We are, &c.,

(Signed) Francois Le Mair & Rivers Hicks,

London, 14th July.

THE FORESTS OF CEYLON.

BY F. D'A. VINCENT.

(From the *Indian Quarterly Magazine of Forestry.*)

The general public probably gets its idea of Ceylon by a short stay on the western side of the island, when the steamer touches at Colombo or Galle, or perhaps by the account given of the climate by some relation who forms one of the large and important community of coffee planters, with estates in the centre of the island. The climate and vegetation of the greater part of Ceylon are so different from those of the western coast and of the coffee districts, that I shall first give some idea of the distribution of the rainfall before mentioning the forest vegetation.

The island is exposed to the full force of the south-west and north-east monsoons ; and, as these monsoons blow for eight months out of the twelve, it would be natural to suppose that the rainfall is both heavy and equally distributed throughout the year all over the island. This, however, is not the case. The south-west monsoon, breaking generally about the middle of May, passes over two-thirds of the island without more than a passing shower, the principal rainfall of the island being that brought by the north-east monsoon.

If the reader will examine the map of Ceylon he will find in the centre of the southern half of the island some ranges of hills extending from Kandy southwards to the Moruwa Korale, within 30 miles of the sea. These ranges of hills, about 60 or 70 miles long, form the eastern boundary of the area affected by the south-west monson. All parts lying to the south-west of these hills share more or less in the downpour, whilst the rest of the island only benefits by an occasional shower. The effect of these ranges of hills is most remarkable, and is probably due to their arresting the course of the clouds, and forcing them back towards the sea. In Colombo, which, it will be seen, is south-west of the northern limit of the hills, the average annual rainfall is 87 inches, whilst at Negombo, 18 miles further north, and rather further from the hills, the rainfall is 66 inches. At Chilaw, only 42 miles north of Colombo, and quite out of the influence of any hills or other obstacles to arrest the course of the south-west currents, the rainfall sinks to 48 inches. On the southern coast the same effect is noticeable. At Galle the rainfall is 90 inches, whilst at Hambantota, 70 miles to the east, in the extreme south-east corner of the island, across which the two monsoons sweep, the rainfall is only 20 inches.

The north-east monsoon begins in October, and, lasting till February distributes its rainfall over the whole of the island, those parts to the north-east of the central mountain ranges naturally receiving most. The hills do not, however, as in the case of the south-west monsoon, protect the lee side of the island, for, at Colombo and on the western side of the island, the winter rains are often the heaviest and most continuous.

The moist zone, or that affected by both monsoons, is therefore comprised within lines drawn south from Kandy to Matara (about 100 miles), and from Kandy to Colombo (about 60 miles). Within these lines and the sea the rainfall varies from 60 to 230 inches, the average being perhaps about 90 inches.

The rest of the island or the dry zone, is affected only by the north-east monsoon, the rainfall varying from 60 inches on the eastern coast to 30 and 20 inches at Manaar and Hambantota, the average annual rainfall for the greater part of the area being about 45 inches.

It will, therefore, be seen that the climate of the greater part of Ceylon presents a vast difference from that of the western parts most visited by Europeans. The limits of the moist and dry zones, which have been thus roughly defined, correspond with the limits of two very distinct floras—that of the moist zone is very similar to the flora of the Malayan Peninsula, whilst that of the drier parts of the island resembles in many respects the flora of the Madras mainland.

As regards the forests I may begin by saying that all the forests are evergreen ; there are very few deciduous trees, and none of them form any important part of the forest growth.

In the moist zone there are few forests left of any extent, comprising the only parts of the island which are thickly populated. Very large areas of Crown land have been sold for plantations of coffee, cocoa, tea and other "new products," also for paddy cultivation. Some of the most important forests have also been sold to private persons, who are to work out the timber and sell it in Galle or Colombo.

The forests, which are still the property of the Crown, form only small isolated blocks. In the moist zone the forests do not generally contain much valuable timber. With the exception of Calamander and Nedun (*Pericopsis*) there are no very valuable woods, but with easy water carriage to the coast, all the softer timbers find a ready sale for in-door work, and for coffee cask staves. The principal woods in these forests are :—*Doona zeylanica, Artocarpus nobilis, Carallia integerrima, Dillenia retusa, Vateria acuminata, Dipterocarpus zeylanicus, Careya arborea, Melia dubia, Pericopsis Mooniana*, several species of *Eugenia, Diospyros quæsita*. The last, Calamander wood, was formerly common in the wet forests with a rainfall of 120 to 150 inches. For cabinet work it is one of the most valuable, but the tree is now almost extinct. Pieces only fit to give planks four inches broad are said to have been sold at the rate of R400 a ton, and it is difficult now to get even a specimen of this beautiful wood.

Timber work at present is principally directed to the dry zone, where there are still very large areas under forest. In the northern half of the island, and in a great part of the eastern province, the population is very scattered ; villages are very far apart, and probably not more than one hundredth part of the area is cultivated. The rest of the country is more or less covered with evergreen forests, and with tree scrub. The principal forest trees are :—Satinwood (*Chloroxylon Swietenia*), Ebony (*D. Ebenum* and *D. Melanoxylon*), Trincomali Wood (*Berrya Ammonilla*), *Mimusops Elengi, M. indica, Alsodaphne semecarpifolia, Vitex altissima, Calophyllum tomentosum*. These form the saleable woods. They are mixed up with a very large proportion of woods which are at present worthless, and almost unsaleable. Most of the forests usually consist of the commoner kinds of wood, with the saleable woods sparingly sprinkled amongst them. The only valuable trees which anywhere form a fair share of the standing stock are Trincomali wood, Satin wood and *Mimusops indica*, and with these it is only in the most favorable situations that any one species forms one-sixth of the standing timber. The following are some of the commoner kinds ; some give very fair timber, but there is at present only a demand for the better kinds of wood mentioned above :—

Schleichera trijuga, Strychnos Nux Vomica, Ulmus integrifolia, Acacia leucophlæa, Diospyros Embryopteris, D. ovalifolia, Terminalia Arjuna, Phyllanthus Emblica, and very many others, such as *Stephegyne, Adina, Dysoxylon, Petrocarpus, Cassia*.

A tree forming a very remarkable feature in nearly all the drier forests is *Hemicyclia sepiaria*. It often forms one-third or even more of the forest, and with its irregular fluted trunk has a very peculiar appearance in large masses. The wood is useless.

The forest soil is generally sandy, poor, and of no great depth, with an underlying rock of gravel, quartz or gneiss. Under the taller trees there is usually a dense scrub, consisting of seedlings of the inferior woods, and of other shrubs, and growing to a height of six feet. With the larger trees overhead and the undergrowth, the soil is completely protected from sun and wind, and its natural poverty is less apparent when enriched by thick layers of leaves. Grass is rare in all the forests, and consequently forest fires of any extent are unknown.

Since 1873 the forests have been principally worked by direct Government agency, but previous to that permits to cut timber were issued to traders on payment. With defective supervision, it is scarcely necessary to add that immense harm was done; we now find that the traders succeeded in clearing most of the forests within 25 miles of the seaboard. There is reason to believe that very large thefts of timber took place, but worse than that, the natural reproduction of the better species has been almost at a standstill for the last 30 years. It is difficult to arrive at the real cause of this, but it is possible due to the fact that the ground was, at the time of the felling, already stocked with seedlings of the commoner kinds of timber. These had been forming the undergrowth for years, only waiting for the opportunity, which the clearing gave, to spring up into vigorous growth.

The forests have, however, a still greater enemy to contend with. Chena or Hen, the Ceylon representative of the Indian Kumri, Jhoom or Tonngya, has perhaps done more harm here than in any other part of the east.

A scanty population of Sinhalese and Tamils decimated by disease and famine, and too indolent to undertake paddy or any other form of permanent cultivation, have, for the last fifty years, been engaged in devastating thousands of square miles of the finest forest in the island, to secure one or two crops of millet or Indian corn. The soil after being abandoned becomes covered with a very dense scrub of *Dichrostachys cinerea*, *Phyllanthus Emblica*, *Zizyphus* (four species) *Carissa*, *Dodonæa viscosa*, and other similar species. This scrub grows about 20 feet high in 15 to 25 years, and then remains until the cultivator returns to clear it again. This he avoids doing until he has exhausted all the available areas, of rich forest land; and, as he can generally manage even now, to find some forest which has never been cleared before, it is rare to find old chena land brought into cultivation a second time. Except on the east coast, grass rarely comes up on chena clearings, so, when seen from a height, the general appearance of the country is most deceptive. Old chena scrub has the appearance of forest, so that looking from one of the many isolated hills of the bare gneiss which are so common in the north-east of Ceylon, the ordinary observer would think he had to deal with one vast forest instead of with a sea of chenas, dotted with a few islands, the remains of old forests. Chena cultivation, and the devastations of the traders combined, has only left the remains of what 30 years ago must have been magnificent forests. The work of restoring these remnants and restocking the forests with the better woods will, I fear, take more than double that time to accomplish.

A large portion of the forest produce is exported to India, China and Europe. India takes Trincomali wood for its gun-carriage factories, for the Madras masula boats, &c.; satin and ironwood for building; palmyra for rafters (cut at present in private lands); *Calophyllum tomentosum*, for poon wood masts and spars; and some firewood.

China takes ebony, the blackest wood only, and of this Ceylon has the monopoly. For the best black ebony the price usually is R 120 to R 140 per ton in Colombo. Satin wood and ebony are sent to England, the English market being less particular than the Chinese as to the color of the latter.

CINCHONA CULTURE IN JAVA.

In the report for the second quarter of 1882, translation of which we publish today, Mr. Moens records an additional fact shewing that a stock plant inferior in the more precious alkaloids has no influence on the graft. This had been already proved in the case of succirubra stocks, and now Mr. Moens has ascertained that a graft of valuable ledgeriana placed on a stock of C. josephiana almost destitute of quinine retained all its valuable properties unimpaired. As we always felt certain would be the case, too, hybrids between the better ledgerianas and succirubras gave bark rich in quinine. Mr. Moens says nothing of their habit of growth, but we see no reason to doubt that such hybrids will generally combine the robustness of the succirubra parent with the richness in quinine alkaloid of the ledgeriana. From its spindly habit, apart from any question of dying off, we found *C. officinalis* in great disfavour in Java. It will be seen, however, that such bark of this kind as was sent to market from the Government gardens fetched prices only second to those realized by ledgeriana bark.

REPORT ON THE GOVERNMENT CINCHONA ENTERPRIZE IN JAVA FOR THE 2ND QUARTER 1882.

The rainy weather continued during the past quarter. There were planted out 14,000 more ledgerianas, of which about 4,000 were cuttings and grafts, and 9,000 succirubras. The partial stripping, favored by the wet weather, was continued. About 120,000 A. lb. of bark have now been cathered, of which, up to the end of June, 108,384 A. lb. facked in 803 bales had been dispatched to Tjicao. The rop of 1881 was sold on 23 May at Amsterdam at the ollowing prices per ½ kilo :—

C. succirubra	...	88c. to 253c.
C. calisaya javanica	...	55c. „ 200c.
C. „ schuhkraft		47c. „ 164c.
C. ledgeriana	...	78c. „ 670c.
C. hasskarliana	...	60c. „ 180c.
C. officinalis	...	264c. „ 410c.
C. lancifolia	...	135c. „ 175c.

The shavings of succirubra were sold at a higher rate than the finest stem bark in quills; for ledgeriana also the highest price, 670c., was paid for shavings. The ledgeriana twig bark realized, according to the yield of alkaloid, which varied from 1·2 to 3·1, from 78 to 229 cents per half kilo. The renewed bark of officinalis fetched 410c. per half kilo. On the whole the prices were in accordance with the yield of quinine, and were very satisfactory. By G. O. of 2nd May No. 13 G. Teekamp was appointed temporary nurseryman, and he entered on his duties at once. Besides the oversight of the extensive nurseries at Tjinirocan he is charged with the making of experiments of different methods of grafting in the open air, and he has already made a beginning with this. It was shown by an experiment with a C. ledgeriana, which was grafted five years ago on the stem of a C. josephiana, that the value of the alkaloids was not altered by the grafting. The ledgeriana bark contained 7 p. c. of quinine, while that of the josephiana stem had 0·6 p. c. The examination of young ledgeriana bark, both from government and private gardens,

was continued. It is shown more and more clearly that when the young trees possess the pure type of the mother tree the alkaloid yield also agrees with this. As the average of very typical four year old plants, descendants of the mother trees 23 and 38, 9 p. c. quinine was yielded. A picked tree, descendent of 23, of that age, contained so much as 11·75 p. c. quinine. A series of experiments was also performed with barks of descendants of C. ledgeriana which from their habit appear to point to a hybridization by C. succirubra. They are usually very rich in alkaloid, sometimes also in quinine, while a yield of cinchonidine often confirms the opinion that they have been produced by a hybridization with C. succirubra. The determination of the alkaloids of specimens of the crop was regularly carried on.

J. C. Bernelot Moens,
Dir. Govt. Cinchona Enterprise.

Bandong, 1st July 1882.

Total trees at 30th June 1882, 3,094,500, viz.:—*in nurseries*: 651,000 ledgeriana (including 6,553 cuttings and gratts), 220,500 suc., 171,800 off.; *in the open*: 650,200 ledger. (including 79,000 cuttings and grafts and besides the more or less 6,300 original ledger.), 491,000 calis. and hass., 443,500 suc. and calop., 457,500 off., and 9,000 lanc.

TEA.

There has been a good demand for the larger supplies of Indian Teas, and a better sale for the medium descriptions, at rather firmer rates for the stronger sorts, since the arrival of the new China crop. Until large shipments of new Indian Teas arrive, a steady market may be expected, especially for the good medium sorts. The reports from most of the plantations of the progress of the new crop continue favourable, and although the season may be somewhat later than the last, the teas will probably be quite equal in quality. At the public sales 8,302 packages were offered, including 917 of Java and 625 of Ceylon teas. The Indian growths were well competed for, at generally firm prices. The quality of the Ceylon teas was inferior to that of some of the previous shipments; but the falling-off, it is to be hoped, is only temporary, as there is no reason, with care, why they should not become as popular as either Indian or China teas, and the industry may in time prove highly important. It is, indeed, reported that the Ceylon crop may reach 1,500,000 lb this year, and the Indian yield, should the weather be propitious, may not impossibly reach 60,000,000 lb. There is thus every prospect of rapidly increasing supplies of teas, especially when it is remembered that only a few years back the Indian crop was less than that of Ceylon now is. The Java teas offered at this week's sales were better than the bulk of the late imports, and consequently there is a good demand for them at improved prices.

The imports of tea into the Kingdom for the month of June were 8,406,570 lb, or nearly double those of the corresponding months in 1881, being an increase of no less than 86·3 per cent., or 3,899,775 lb. For the six months the imports were 63,842,543 lb against 61,355,386 lb, an increase of 2,487,157 lb, or 4·05 per cent. The deliveries for home consumption for June were 12,865,130 lb against 11,667,572 lb, an improvement of 10·26 per cent., or 1,197,558 lb, and for the six months the consumption was 79,462,523 lb against 79,043,651 lb, a slight improvement of 0·52 per cent. or 418,872 lb. The total deliveries from the 1st January were, however, materially smaller, as the exports for the six months have fallen off to the extent of 3,657,063 lb, or 20·68 per cent., though those for June compare very favourably with the corresponding month last year, as they were 295,547 lb, or 11·90 per cent. in excess. The totals were 14,026,815 lb against 17,683,878 lb, and 2,777,882 lb against 2,482 335 lb respectively. The stock on the 30th ultimo was 83,672,350 lb, against 69,564,254 lb on the same date in 1881, an increase of no less than 20·28 per cent., or 14,108,096 lb.—*Produce Markets' Review.*

Economic Plants.—Mr. Roberts of Galle, Ceylon, is in receipt of seeds of the following plants, viz., *Cinchona Calasaya Morada*, the choicest description of cinchona cultivated in Bolivia, *Soma Cotton* a very valuable variety, *Coca*, *Quinoas*, *Pacuo* and *Yngas Coffee*, considered to be the finest flavoured coffee in the world, *Maize Blanc*, the best variety of the wonderful *Cusco* or *Yncos* Maize, and has offered them to Government for sale at R500 per ounce, R150 per lb. R200 per lb., and R200 per lb. respectively. Government have referred the matter to the Board of Revenue, the Conservator of Forests, the Honorary Secretary of the Agri-Horticultural Society, and to the Superintendent of the Government Central Museum. —*Madras Times*.

The Potato Crop on the Nilgiris.—The continuous rain and damp that has prevailed since the beginning of June without intermission for nearly two months has caused serious injury to the prospects of a fine potato crop. The young tubers have rotted wholesale in the soil, and the growers are taking up as rapidly as they can what is left of the crop, and throwing them into the market in an immature state. This immaturity can easily be detected. The skin is very light colored and thin, while the potato when boiled does not crumble, but is sodden and wanting in flavor. A great scarcity of potatoes will arise, if the crops elsewhere are destroyed in the same way as in the neighbourhood of Ootacamund. Seed potatoes will also be scarce, as little that is now being rooted up can possibly keep till next sowing time comes round.—*Madras Times*.

Ceylon Tea.—We observe, our townsman, Mr. Maclaren, of Messrs. William Moran & Co., has been laid hold of on his way through Colombo, and induced to look at a large number of Ceylon tea samples. This is one of the penalties of greatness, and, as Mr. Maclaren has made a name for himself in connection with tea, he must not be surprized if he be interviewed in this manner. He was able to give an encouraging opinion of their produce, which must have been very satisfactory to the island planters. We are told he valued none of the samples under 1s 2d, and some as high as 2s 4d. If none were under 1s 2d, we imagine they could not have been a fair average assortment of samples. They must have been only high-class teas; at any rate, as the result of this examination, we shall expect Ceylon to take a higher rank in Mincing Lane this year than she has hitherto done. We are afraid that the mistake made by Ceylon is in planting out tea as an appanage to a coffee plantation leaving its cultivation and manufacture to the coffee, manager and his establishment. This will not do: both treatment of the two plants being so diverse, in order to give the tea anything like fair play, it must have its own trained establishment. The former mode may be excusable, when only a few acres are planted for experimental purposes, but, if Ceylon wishes to take her place among tea producing districts, she must grow and manufacture her crop on more intelligent principles. Mr. Maclaren complained of over and under fermentation, and of over-firing. Fermentation being one of the most important processes in manufacturing would seem not to have received that attention it deserves. These facts all go to prove what we have said; that the growing and manufacturing of tea must be superintended by gentlemen who have given attention to the subjects, and not by coffee planters whose experience has been in another direction.—*Indigo Planters' Gazette*. [But there is nothing in the world to prevent an intelligent coffee-planter mastering the mysteries of tea manufacture. Many have qualified themselves and others are learning. Unhappily, on a large number of coffee estates, the quantity of coffee recently produced has not been such as to demand the exclusive attention of superintendents.—Ed.

Correspondence.

To the Editor of the Ceylon Observer.

COFFEE ADULTERATION:—SHAMEFUL ATTITUDE OF BRITISH OFFICIALS.

38 Mincing Lane, London, E.C. 14th July 1882.

Dear Sir,—I beg to hand you a statement hastily penned, showing the present position of the coffee adulteration question, and the shameful way in which the Government appear to be withdrawing from their pledges and promises. I have no doubt that this breach of faith will arouse a deep feeling of indignation throughout the colony, and I hope that the coffee planting interest in Ceylon will strengthen our hands in the fight, which we have no intention whatever of giving up, to obtain redress in a righteous cause and the reversal of legislation, which is a scandal and a disgrace to this country.—I remain, dear sir, yours faithfully, H. PASTEUR.

38, Mincing Lane. London, 14th July 1882.

On the 20th January last the Treasury, at the request of the Board of Trade, and against the strongly-expressed opinion of the Board of Customs, issued a minute sanctioning the importation of "coffee or chicory, roasted and ground, mixed, without reference to the proportion of the mixture, and of any other vegetable matter applicable to the use of chicory or coffee." This order led to an indignant protest on the part of the coffee trade, whose memorial, signed by all the most influential firms representing its various interests, was addressed to the Treasury, followed by the urgent representations of its delegates, and of the Council of the London Chamber of Commerce, and the Financial Secretary of the Treasury, promised that the obnoxious order should be reconsidered.

On the 24th of April, Mr. Gladstone, in his budget speech, spoke as follows:—

"The revenue derived from coffee in 1867 yielded £390,000; the coffee duty was reduced in 1872 from 3d to 1½d per lb., and in 1874 it only yielded £207,000. But while the great movement adverse to alcohol, which has been so eminently favourable to both coffee and chicory, has been at work since 1874-5, it has not produced the slightest rally in the revenue from coffee, but on the contrary, during the last seven years, there has been a further diminution in coffee. In 1874 the coffee duty was £207,000; in 1881 it was only £189,000; and, although the chicory duty had been slightly increased, it only increased by £8,000, and did not make up the whole difference. When we turn to tea, the case is very different. There it is not in the tea houses, but the domestic use of tea that is advancing at such a rate that there you have a powerful champion able to encounter alcoholic drink in a fair field and to throw it in fair fight. The revenue on tea, which in 1867 was £3,350,000, had risen in 1874 to £3,875,000, and in 1881 to £4,200,000. The increase of the population during that period of 14 years was 4,900,000. But there was no corresponding augmentation in the revenue from coffee and chicory. I am bound to say there is a peculiar state of the law to which I ought to invite the House to apply a remedy, and I shall lay a resolution on the table of the Committee this very evening with that view. At present every description of admixture with coffee is permitted and we have long proceeded on the principle that the admixture of chicory with coffee was not adulteration—that it was an admixture rooted in the habits of many countries so that people would not drink coffee without it. But of late a practice has grown up of producing all kinds of substitutes under the name of coffee, and that, I cannot but think, must in some degree account for the strange and singular state of the figures that I have laid before the Committee. We shall not attempt to interfere with the admixture of chicory with coffee, but we propose that it should not be allowed to introduce other miscellaneous admixtures with coffee."

Mr. Gladstone, that same evening, laid on the table of the House the following resolutions, viz:—

1 "That the Duty of Excise on vegetable matter grown in the United Kingdom applicable to the uses of chicory or coffee (other than chicory) shall cease to be payable, and the sale or exposure for sale of any such vegetable matter in imitation of, or mixed with, chicory or coffee shall be rendered illegal.

2 "That the Duties of Customs on vegetable matter applicable to the uses of chicory or coffee (other than chicory) shall cease to be payable, and the importation as merchandise of any such vegetable matter mixed with coffee or chicory shall be prohibited.

3 "That it is expedient to amend the law relating to the Inland Revenue and the Customs."

A fews days later the Customs and Inland Revenue Bill was printed: that Bill, prepared and brought in by Mr. Playfair, the Chancellor of the Exchequer, and Lord Frederick Cavendish, contains the following clauses:—

3 "The Duties of Customs on vegetable matter (other than chicory) applicable to the uses of chicory or coffee shall cease and determine.

4 "The importation of any article or substance whatsoever prepared in imitation of chicory or coffee, and called by any name of or mixed with chicory or coffee is hereby prohibited, and such preparations or mixtures shall be forfeited and may be destroyed or otherwise disposed of as the Commissioners of Customs shall direct.

6 "If any person shall keep for sale, or offer or expose for sale any article or substance whatsoever prepared or manufactured for the purpose of being in imitation of or in any respect to resemble chicory or coffee, or to serve as a substitute for chicory or coffee, or which shall be alleged or intended so to be, or shall be mixed with or called by any name of chicory, or coffee, such article or substance, and any chicory or coffee with which it is mixed, shall be forfeited, and may be seized by any officer of Inland Revenue, and the person preparing, manufacturing, or selling the same, or in whose custody the same is found, shall incur a fine of *one hundred pounds*."

Evidently at that time Mr. Gladstone recognized the justice of the complaints of the coffee trade against the recent Treasury minute, and his speech and the clauses of the Bill show that he also realized the gross injustice and unfairness of the unprincipled adulteration which had gradually been allowed to be practised in that trade. The Customs and Inland Revenue Bill was, however, set aside, under the exigencies of the Clôture resolutions, and of the Irish and Egyptian questions. Still, relying on Mr. Gladstone's promises, the trade waited patiently for the passing of the Bill, which was but an act of partial and tardy justice, when, to the surprize and indignation of all, the new financial Secretary of the Treasury, Mr. Courtney, between 2 and 3 o'clock in the morning on the 8th inst., in Committee of Ways and Means, without previous notice, rose to propose on behalf of Government the following resolution:—

"There shall be granted and paid to Her Majesty, her heirs and successors, upon every half-pound weight of any article or substance called by any name of coffee or chicory, or prepared or manufactured for the purpose of, being in imitation of, or in any respect to resemble or to serve as a substitute for coffee or chicory, which is sold or kept for sale in the United Kingdom, and also upon every half-pound weight of any mixture of such article or substance as aforesaid with coffee or chicory, which is sold or kept for sale in the United Kingdom, the duty of excise of one penny."

To the protests of one honourable member, Mr. Gladstone observed that the Treasury were concerned with the collection of the revenue, and not with adulteration. One is at a loss to qualify such an extraordinary and arbitrary proceeding. In ordinary life it would be called a breach of faith; on the part of the Chancellor of the Exchequer who, in his financial statement addresses himself in the name of Government to the whole country, and to its colonies and dependencies all over the world, and, bearing in mind the words of the Chancellor, and the terms of the Bill embodying his views and those of his Government, it is a violation of a distinct pledge and promise, without one single word of explanation. Mr. Gladstone does not even condescend to say that he has changed his mind since the 24th of April; he probably has not changed his mind, but is prevented from doing what he considers himself as an act of justice, by the pressure of his friends of the Board of Trade, and of those clever and industrious individuals who have been earning their living by mixing *duty free* malt, or ground date stones, or dandelion root, or other rubbish, with *duty paying* coffee, and selling the mixture at the price of genuine *duty paid* coffee, using the name of *coffee*, to which they tack on that of their special pet article, so as to attract an unsuspecting public, and realize profits which could not be secured if they attempted to sell their manufacture under its real name.

It is an unworthy excuse, or rather it is an evasion and not an excuse, to reply, as Mr. Gladstone has done, that the Treasury is concerned with the collection of the revenue and not with adulteration, when he has stated himself in his budget speech that "*the practice which has grown up of late of producing all kinds of substitutes under the name of coffee, must in some degree account for the strange and singular state of the figures that he has laid before the Committee, and for which he invites the House to apply a remedy*;" in other words, Mr. Gladstone recognizes that owing to those adulterations the revenue from the coffee duty has decreased, and a remedy must be applied to restore the productiveness of that source of revenue. Such, no doubt, is the duty of the Treasury, and such would have been the effect of the clauses of the Customs and Inland Revenue Bill, which have just been thrown overboard by Government to please their interesting friends and protégés in the Channel Islands, Liverpool, Aylesbury, and other centres of the industry of coffee mixtures.

Mr. Gladstone praises those *valuable and useful institutions, the Coffee Taverns and Tea Houses, which are encountering alcoholic drink in a fair field, and may throw it in fair fight.* Tea has and always has had all his sympathies, its sale is guarded jealously by regulations, no admixture whatever is permitted; woe to the offending retailer! Tea has a fair field; it looked at one moment as if coffee would also have an equal chance provided chicory was mixed with it, but now coffee is not to have a fair field, but is to be handed over to the tender mercies of manufacturers of horrible mixtures, and adulterations

of the most reckless description, under which it will probably disappear some day as an article of consumption in this country.

The baneful effects of the Treasury minute of 20th January, to which Government appear to have practically adhered, cannot be better described than in the terms of the memorial of the Chamber of Commerce to Mr. Gladstone praying for its withdrawal, where it is described as a "tacit admission and encouragement of indefinite adulterations, and as containing indications contrary to all principles of integrity and honesty." It appears, however, that Government consider that they have no concern with the morality of a thing, so long as *an honest penny* (?) can be earned by doing it.

H. PASTEUR.

ANALYSIS OF CINCHONA BARK.

London, E.C., 21st July 1882.

DEAR SIR,—On page 510 in your overland issue I find you conclude a letter by saying: "What a pity the medical officers in planting districts are not qualified analysts, to help the cinchona industry."

There are several known methods of testing the value of cinchona, and when one of your Ceylon planters was at home he came to me to enquire if he could be taught the process. I introduced him to a friend of mine in Paris, who, in about a week, educated him by a very simple method to test the value of the different samples of cinchona. There are many young chemists who would be thankful to qualify here or in Paris and go out to Ceylon, and, if they received a small fee for each analysis, they ought to make a good living. With constant practice the test is very quickly made, sufficiently good for a planter's guide.—Yours truly,

THOS. CHRISTY.

CINCHONA AND LIBERIAN COFFEE CULTIVATION IN THE LOWCOUNTRY.

Kalutara, 22nd July 1882.

DEAR SIR,—The cinchona question is occupying so much attention at present that a few details of some experiments in Kalutara will be interesting to you and your readers.

On this estate, plants of C. succirubra, ledgeriana, pubescens and condaminea were put out a little over a year ago, and the three latter varieties are all doing well, being on an average from 3½ to 5 feet high. The first-mentioned is not doing well here, but on the other estates at an elevation of 500 to 700 feet it is looking remarkably well for its age.

The elevation, here is only 200 feet above sea-level, and there has, so far, been no dying out, except on a little flat, where, through damp, a number of plants have failed. All the plants on the estate were reared in Barnagalla nurseries, in Doloshage, and none died from the effects of the long journey down.

The foregoing facts open a field for investigation among our cinchona savants, as C. succirubra has heretofore (I understand) been supposed to be the variety suited best for low elevations.

The pubescens has flowered freely, and one or two of the ledgers, but the others have no tendency to do this. I send you, under separate cover, some flowers of ledgeriana and pubescens type and leaves of both and condaminea too.

Curiously enough I noticed a ledger plant covered with black bug. The latter looked exceedingly fat and happy: probably from the medicinal effects of the foliage they were feeding on?

That Liberian coffee on selected land will pay handsomely, there can be no doubt. A small clearing (5 acres), the first opened on an estate here now 3½ years old, will, within its fourth year give 100 bushels parchment: already 60 bushels have been dispatched. This is about 4 cwt. per acre planted 10 × 10 feet; but at 7 × 7 feet, which is the distance most people have now adopted, it would give 8 cwt. per acre: not a bad maiden crop in those hard times?—Yours faithfully, W. L. F.

ENEMIES OF CARDAMOMS.

August 8th 1882.

DEAR SIR,—In answer to several enquiries as to what grub or other insect bores the holes in cardamom seed, I now send you the grub as caught in the act of boring a seed and the seed with it. Perhaps you will be able to describe the same. This grub lives among the cardamom bulbs and is difficult to get hold of. A mixture of ashes and lime applied among the bulbs is the only thing I find that stops the grub from doing the mischief, but whether it kills the brute or whether it jumps out of its nest and goes somewhere else I cannot say, as I have not found a dead one yet: this grub jumps forsome distance.—Yours truly,

J. HOLLOWAY.

[The well-known destructive wireworm. It is the larva of a beetle belonging to the family Elateridæ. Curtis, in his "Farm Insects" says:—"These beetles have been called elaters from a peculiar power they have of leaping up like a tumbler when placed on their back, and for this reason they have received the English appellation of spring-beetles, and skip-jacks, and from the noise which the apparatus makes when they leap they are called snap or brick-beetles and likewise blacksmiths." The same authority gives the following description of the grub:—"The wire-worm very much resembles the mealworm; it is of a pale ochreous colour, becoming darker when dead, with a few hairs scattered over its polished shining skin, it is semi-cylindrical, the back being convex, the belly more flat; its head is flattened or wedge-shaped, and there are twelve abdominal segments. Of all the insect enemies with which the farmer has to contend, there are none which are more fatal in their effects and more difficult to overcome. Refuse lime of gas-works will banish the wire-worm. —Soot and lime will kill them." The little book on "Garden Pests" gives a short description of them at page 76.]

TEA FROM CUTTINGS: THE WEEDING AND DRAINING OF PLANTATIONS.

DEAR SIR,—Can you, or any of your readers, state whether tea has been grown successfully by planting it from cuttings? That they strike rapidly and without any trouble I know from experiment, but I should be glad to hear whether it has been ever attempted on a large scale. I have read with much interest the letter about weeding and loss of nitrates in the soil, etc., by "X.," in your issue of the 5th inst. One thing is certain, namely, that our system of cultivating in Ceylon by keeping the surface of the land bare with monthly weeding and cutting open surface drains across our hillsides is unique and not adopted in other countries, even where labour is plentiful, either for coffee, tea, or cinchona. How can it be proved that the results are in our favour, or that estates previously dirty and undrained have given larger crops since they have been cleaned and thoroughly drained? With regard to drainage I believe sentiment and association have had a great deal to do with the general way in which it has been carried out. A. at home is pleased to see in the report he receives that his estate is now all thoroughly drained, and possibly is sorry when told that his neighbour B. is likely to be ruined and have his estate washed away, because he has not had a drain cut in it. These surface drains and drainage as carried out on land at home have widely different effects, and with our tropical bursts of rain I am inclined to think B. is better off than A. Another circumstance which is seldom taken into account when ordering a estate to be drained is that the cost of constructing these drains is nothing to the ultimate expense of clearing and

keeping them in repair. After heavy bursts of rain, and with short crops and several miles of drains to keep clean, the work is not done, and wash is intensified though expenditure be kept down. Draining has been carried out now nearly universally upcountry, and if drains be the means of stopping wash, how is it that as soon as there is a heavy burst of rain all the streams and rivers become immediately discoloured?

J. L. A.

ABNORMAL SEASONS AND NOT LOSS OF NITRATES (FROM EXCESS OF WHICH COFFEE TREES OFTEN SUFFER) THE MAIN CAUSE OF SHORT CROPS.

August 15th, 1882.

DEAR SIR,—Your correspondent "W." with his wonted acuteness observes, that "the secret of the hidden ailments under which our coffee is suffering is embosomed in those spots where fertility still stands in strange contrast to surrounding fruitlessness."

I believe that that secret is to be traced to unfavorable climatic influences, very frequently combined with exhaustion of soil. I do not seek to explain all the subtle influences comprised in the word "climate," but only to point out some of the more obviously unhealthy conditions which are induced by unfavorable seasons.

Let us consider what are the conditions necessary to the production of good crops: they are three—good climate, good soil, and judicious cultivation, and the most important of these is *climate*: if we have poor soil it can be ameliorated by cultivation, but over climate we have no control, though we may to some extent modify its influences by cultivation. Climate is synonymous with season.

As a proof of the effect of climate, I would instance the Udapussellawa district, which, with the exception of a few estates, is by no means remarkable for its richness of soil, but with its wonderfully favorable seasons it has produced some of the best crops seen in recent years. Unfavorable seasons produce unhealthy conditions: in a season of too much rain during the blossoming period nitrification probably proceeds too rapidly, and the tree unless provided with an abundant supply of soluble mineral food, absorbs too large a proportion of nitrogen, which induces an over rapid cell formation; consequently the tree runs to wood, the sap of which is ill-nourished, so that, even if blossom is formed, it does not set; the tree too, being weak, is in the most receptive condition for the attack of leaf disease and other enemies. It is noticeable that coffee, as it were disappointed by an unfavorable season in its desire to crop, appears to be thrown off its balance, the wood which intended to blossom is spoilt, and the tree makes a further effort towards reproduction, pushing out an abortive spike out of its proper season, which further exhausts the tree. These disturbed conditions above soil probably indicate an equal disturbance below, and the balance once destroyed is not easily restored, though even a good season may follow upon the bad one; it is probable therefore that a diseased condition of the roots is induced which it will require a succession of good seasons to restore to health: such a succession of seasons it has not been our good fortune to experience for the last 10 or 11 years; now—even given the return to normally favorable seasons—we should have to suffer from the weakness following upon low cultivation and want of conditions of fertility in the soil.

In order to arrive at conditions favoring the utmost fertility it appears reasonable to suppose that a proper balance must be maintained between the mineral and nitrogenous supply of food, and that therefore in a wet season, when nitrification is proceeding rapidly, giving an over-abundant supply of nitrogen to the tree, the effects of the season may be considerably modified by adding artificially to the soil a supply of mineral food with little or no nitrogen; in an over-dry season or hot climate, the process being reversed. Doubtless on such estates as are favored with a limestone formation, the supply of mineral food is better sustained alongside that of nitrogen, than on the majority of estates, which are without this natural advantage, wherein is contained a hint as to the artificial addition of lime.

In unhealthy condition of soil is, I believe, to be found the explanation of the grub pest, a sort of fermentation being very possibly set up, which would provide the grub with fungoid food, and if this hypothesis were correct, until the conditions were removed there would be little hope for the departure of the enemy.

Though the subject of nitrification will no doubt be more ably handled by Mr. Wall and others, still, as bearing incidentally upon my subject, I hope that "X." and your other readers will pardon me if I touch upon a question which I have frequently had under consideration.

If the deductions of "X" from Mr. Warington's paper on the Rothamstead experiments were correct, the first exhaustion from which our coffee trees would suffer would be want of nitrogen, whereas the presumption is that, the reverse is the case, seeing that the trees still retain the power to make wood, and that the measure of restored fertility is mainly in proportion to the amount of phosphate in the manure. "X." has overlooked the very material difference between subsoil drainage by covered pipes and our own system of surface drains: by the former the rain water is drawn through the soil by the suction of the pipes and carried off to the streams, while by the latter, after the complete saturation of the soil, only the superfluous water runs off. The nitrates therefore would only be carried down to the subsoil to be taken up again by the roots as soon as they had struck down to it. In a bare fallow such as our clearings present for the first year or two after the burning off of the jungle, the surface soil would naturally become considerably exhausted of nitrogen and be in an unfavourable condition for the support of young plant-life; still in our tropical climate there is probably much compensation for the loss sustained by heavy rainfall. In the exhaustion of nitrogen in the surface soil I am of opinion that the reason is to be found why supplies fail to such a large extent after the first few years of a plantation's existence,* and also why cinchonas do not grow on a second planting.

To sum up, my contention is, that to abnormal seasons producing unhealthy conditions and a disturbed balance we mainly owe our present infertility. By abnormal seasons I would be understood to mean rain or drought occurring at the wrong time of year and not that a heavy rainfall or a prolonged drought at the proper season does us any great amount of injury: on the contrary I consider that in the present heavy rainfall lies the chief promise for a good crop next year upon such estates as are in a *condition to avail themselves* of a good period of blossoming weather.

Secondly that good cultivation, which means judicious use of manure and tillage of the soil, is capable of modifying to a considerable extent the ill-effects of abnormal seasons and giving us immunity from other pests.

And further that it is not to loss of nitrates that we are to look for the explanation of our present short crops.—I remain, dear sir, yours faithfully,

W. D. B.

* But there is great force in the popular planting belief that the main reason why supplies fail is that the feeding rootlets of the established plants enter the stirred soil and rob the supplies of their nutriment.—ED.

CRANLEY CROWN BARK FROM TREES 6 YEARS (SECOND SHAVING) YIELDING 6s 10D PER LB.—THE LOCAL AND HOME MARKET.

Cranley, Agrapatana, 16th Aug. 1882.

DEAR SIR,—I have much pleasure in informing you that the officinalis trees on Upper Cranley, the bark of which fetched such a fair price, are about 6 years old. This is second shaving and was performed about 11 months after the first, the increase in quantity being about 20 %. The analysis of the original bark was only 1·96 % sulphate quinine, which realized 3s per lb. You will be surprised to learn that R1·75 per lb. only was offered for the renewed bark in the local market.—Yours truly, C. R. P.

ALOES &c. AS HEDGE PLANTS.

Mysore.

DEAR SIR,—I read in your last volume, *Tropical Agriculurist*, a letter from "Ledgeriana," asking what would be the best thing to plant round a clearing as a hedge, and in an editorial I see you advise him to try aloes, but you doubt whether they would make sufficient growth in the time required. Of course they greatly depend on the plants when put out. If you can get them grown a foot to nine inches they would—I am speaking from experience—reach the height of about 2½ to 3 feet at the expiration of two and a half years. To begin with: a drain should be dug all round the clearing, say 1½ foot deep, and the mud taken from the drain thrown on, or rather neatly piled up on the off side, that is the side opposite to clearing. On this loose earth the aloes should be planted about 1½ feet apart; no more: less, if you have enough plants. Let them have plenty of air and light, and do not allow them to get choked and overgrown, and they will grow rapidly. The reason for the drain is because aloes, as I daresay most of your readers have noticed, are very injurious to coffee. One seldom sees good trees within 8 or 10 feet of a hedge, and also the great tendency they have of spreading. So much for aloes.

We in Coorg use all kinds of hedges: rose, stakes and lantana, though very few are foolhardy enough now to use the latter and wire. Rose hedges are made by sticking cuttings about a foot long on the ground crossways, and they very soon shoot and make a fair hedge, with a tendency, however, to get gaps in it through some cuttings dying; it also requires a lot of trimming, or it gets very straggly. Stake hedges are simply large cuttings or stakes of some good tree that will grow from cuttings. Stick in about 1 yard apart with strips of bamboo nailed across them just like a post and rail paling. By the time the bamboos are rotten the cuttings, which should be about 5 feet long (one feet in ground), will have shot out all over; then only a little judicious pruning is required. This is all very well for 2 or 3 years, but after that they (the stakes) get into regular trees, and the shade necessarily very heavy. As for lantana, the only advice I can give to those thinking of planting it is—do not. Wire of course needs no explanation.

By the way, I should be much obliged if any one of your correspondents will let me know what is the best remedy for, and what causes, a small clearing of ledgeriana I have to gradually lose all their leaves except the top pair—apparently eaten away by caterpillars, but on examination dell a one can you find. The soil is a fair one, land quite level, but they do not seem to grow a bit. P.

WHAT AILS OUR COFFEE TREES?

SIR,—It has already been shown in a previous letter that infertility prevailed generally throughout the coffee districts in 1871 before leaf-disease had appeared in any force; that even after the fungus had attained its fullest development, good crops sometimes followed its very worst attacks: and utter failure of crop ensued in spite of almost complete exemption from attack; and, finally, that there has not been any such correspondence between the attacks of *hemileia* and the failures of crop, as would certainly have existed between cause and effect. The case as against the fungus must therefore be dismissed, unless as an accomplice after the fact.

Let us then put "*abnormal seasons*" on their trial. Many planters believe that in them is to be found the prime cause of our misfortunes.

The first step in our enquiry must be to define what is meant by *season*. The term admits, on the one hand, of a practical and comparatively simple definition, comprizing only such elements as are familiar to us all; or, on the other hand, it may be so stretched as to involve other forces of which we have no definite knowledge, and may thus become vague and confusing. The practical farmer understands the term to comprize rainfall, wind, temperature, and direct solar influence. He speaks of the seasons as too *wet*, or too *dry*; the rain failing when it was wanted or falling when it was neither expected nor required; as coming in torrents, or drizzling continuously. He remarks on the direction, force and fickleness of the *wind*, its stormy outbursts, or its persistent drift. He notes the degrees and changes of the *temperature*; and takes cognizance of the variations of sunshine and clouds. But he knows nothing of *sunspots*, has probably never heard of *ozone*, and has no other knowledge of *electricity* than what he sees in thunder showers or the electric light. It is not denied that these are all real and powerful forces, and there may be others yet unknown to us in operation; but, as we have no knowledge whatever of their relation to agriculture, we should gain nothing, but only confuse everything by speculating about them.

With regard to *sunspots*, Herschel thought they had a direct influence on agriculture. He believed that, when spots were most numerous, they had an adverse influence on vegetation, and *vice versa*. Careful and prolonged observation has proved the existence of cyclical variations in the number and magnitude of these wonderful phenomena; and they are believed to culminate in periods of about eleven years. As panics or crises in the Commercial World have latterly succeeded each other in somewhat similar cycles, an attempt has been made to connect the spots and the crises in the relation of cause and effect. The result has as yet proved more curious than conclusive. In fact, all that is yet known of these solar disturbances is that they are gaseous outbursts, of the nature of explosions, on a scale so stupendous as to far surpass our powers of conception. They are believed to affect the magnetic currents of the earth, but, as to their influence on agriculture, nothing whatever is known. In the question of the infertility of our coffee trees, however, sunspots may be fairly set aside; because the coffee enterprize has existed through more than 3 entire cycles, and has shown no such periodical variations either of the fruitfulness or growth of the trees as would correspond with those cycles. There was a maximum period in 1860, when our coffee was most flourishing. Another culmination succeeded in 1870, which certainly preceded our first disaster, but it was followed by a minimum in 1878, which so far from inaugurating a return of fertility began the worst part of a cycle which has grown in intensity, and has attained its highest development in this most disastrous year of the decade!

Reverting, however, from things speculative to others familiar to our experience, what abnormal features have our seasons manifested since 1871 to lend sanction

to the idea of their having caused the ruinous infertility we now deplore?

Adopting for our enquiry the practical and simple definition of the term *season*, as already described, what are we to understand by a *normal* season? There has not been, during my long experience of the coffee districts, any such regularity of season as *theory* prescribes. The changes of monsoon, and the weather these changes are expected to bring about, have not occurred with the punctuality and precision that theory lays down. In my experience irregularity in all detail has been the rule, and punctuality the exception. If, therefore, seasons which have deviated from the theoretical law are to be accounted *abnormal*, nearly all that I have witnessed would come under that category. But, setting aside details, both of date and character, those seasons may fairly be regarded as *normal*, in which the monsoons have set within two or three weeks, one way or other, of the theoretical date, and with a fairly good rainfall, both as to quantity and distribution. And those seasons only would be excepted as *abnormal*, when the monsoons have failed, or when one monsoon has materially invaded the precincts of its opponent, or when the months which should be dry have proved wet, and *vice versa*.

Of all periods of the year, the blossoming months are those to which the planter looks most anxiously. Practically, the idea of season in the mind of the planter is almost concentrated upon and confined to those critical months during which the spike is forming, and the blossoms setting. At other times the coffee bush withstands great vicissitude of season without material suffering. Severe and prolonged droughts during the crop-bearing months may affect the filling of the bean, and the ripening of the fruit, but it is in the blossoming months that the effect of the weather is *critical*. If the months of January and February of one monsoon, and August and September of the other, be hot and dry, and, if there be a fair rainfall in the intervening months, the planter may be said to have good normal weather. But, on the other hand, persistent rain in the blossoming months is most adverse, and is even worse, perhaps, than the want of rain in the months which should be wet.

Now, it is matter of history that the critical months of the present year were of the worst. The rain in January and February was persistent and heavy. The usual heat and dryness were wholly wanting, and the blossoms were therefore poor and scattered. Under any circumstances such a season would necessarily have proved adverse: nevertheless, it would be wrong and misleading to attribute the failure we now witness to this cause alone; because seasons similar in this respect, and even worse than this, occurred in former times without producing effects at all comparable to the failure of this year! Moreover, if we were to assume this failure to be due to the adverse blossoming season, how should we account for the failure of the crops of previous years? It seems impossible to attribute a failure of crops so general as that of this last decade, to a cause which has operated so partially, and which past experience proves unequal to produce so terrible a result. The same appeal to experience of the past months enables us to answer the question as to the effects of season generally; for there has not been any such special feature of the seasons since 1870, as has not been witnessed in former times, when their influence went no further than to slightly impair our crops. It is in fact within our knowledge that seasons similar in all observable respects to those of the past decade produced no such disaster as we now suffer, though they doubtless caused some loss of crop!

Without taxing your readers' patience by any attempt at detailed analysis of all the elements of season during the past decade, it may, I think, be confidently alleged that there has not been any single element, nor any combination of elements, recognizable in the seasons since 1871, but such as had been experienced before that fatal year. It does not appear reasonable or possible, therefore, to refer a result so widely diverse from all our previous experience to causes which were in operation then.

If, however, for the sake of argument, it could be conceded that all the blossoming seasons had been adverse since 1870, how should we account for that falling of immature fruit in advanced stages of growth which has so strikingly characterized the period of infertility we are now discussing? Or, to what cause should we attribute that novel feature of the past decade which is to be seen on our finest estates, in the most favoured districts, and on the strongest coffee trees in the shape of abortive fruit? After a fine healthy-looking spike has burst in good weather, and has set, to all appearance, well, how comes it that two or three months after the blossom, its only representative remaining to be seen is a berry here and there amongst a multitude of abortive stalks! And this, alas! is no uncommon case: it is to be seen everywhere. In former times, in one or two extremely wet districts, where the soil was cold and clayey, the fall of immature fruit was often seen, but the abortion which has lately become so fearfully prevalent has affected our trees without regard to soil, climate, or apparent vigour of growth. This is a new phenomenon without any parallel in the history of the coffee enterprize prior to 1871.

For such results as we have experienced during the last decade, it seems to me that no vicissitude of season, nor any abnormal features of the weather which we can recognize, will at all adequately account.

Seasons have been sometimes adverse, and, so far as they have operated, they have helped to aggravate our misfortune, but, when all reasonable allowance has been made for any effects they were capable of producing, there remains a terrible balance of disaster for which they will not account.

The object sought in asking the question "What ails our coffee trees?" is, if possible, to dissatisfy the planters with those reasons which have been too commonly and too long accepted; and to direct their researches and efforts to the discovery of the real origin of the evil. Whoever clings to an erroneous theory raises a barrier against the truth, and, if all these barriers were removed, there would at least be a free and unobstructed course for research. W.

THE CEYLON COMPANY (LIMITED): THEIR TEA AND TEA BOXES.

Colombo, 21st August 1882.

And now, for the benefit of your readers and shippers of tea in particular, I will make you a present of a piece of information which may be of service to them. It is quite true that some of our teas, and other people's teas too, most unfortunately, did go home in boxes which, when they arrived in London, were found to have an objectionable odour, and we have suffered some loss in consequence, both in replacing the objectionable chests with others, *and in liberal allowances to our constituents* for supposed depreciation to the tea carried in those chests, notwithstanding that, as stated in my letter of 19th inst., these very teas competed successfully with Indian teas sold at the same date, and it was difficult therefore to suppose they could have suffered any appreciable depreciation through the lead linings, from the effect of the wood. So jealous is this Company that the reputation of Ceylon teas and the pockets of their constituents should not suffer from any error of judgment of theirs, however unforeseen. The wood of which these boxes was made was buckme—a very good-looking, cheap, light, and workable wood, and we and others had used it for long,

without the slightest objection being raised to its odour. As a matter of fact, it has no odour when properly seasoned ; but we find that, when it has been for any length of time in water in a green state, it acquires a very powerful and unpleasant odour, which, though disappearing almost, if not entirely, as the wood becomes dry, reappears when it is again subjected to moisture, or the steamy atmosphere of a ship's hold. As I said before, I find that others have used this wood as well as ourselves ; and I know of chests composed partly of other woods and partly of bucknee, of which, however, a single board in its offensive state is quite sufficient to infect the whole box ; my object in mentioning this now is that others may profit by the experience we had to pay for.—Yours faithfully, C. W. HORSFALL, *Manager.*

MR. STORCK'S TREATMENT OF COFFEE LEAF DISEASE.

TO THE EDITOR OF THE "FIJI TIMES."

SIR,—When republishing my letter in the "Gardeners' Chronicle" of February 18th last, on my system of permanent vaporisation for the cure of the coffee leaf disease, you were not aware that a portion of it, the introductory matter, and upon which I placed peculiar value as showing the train of thought which led me to my invention, was only referred to as "reviewing previous attempts that had been made." Although I have upon general grounds no reason to complain of adverse criticism from such an authority as the "Gardeners' Chronicle," the editorial remarks contain what may be misleading to others in what it says about the "depth to which fungus may penetrate." I now send you copy of a summary of the part omitted, which please be kind enough to give space in your next issue.

In some of his remarks upon coffee leaf disease, Dr. G. H. K. Thwaites, of Ceylon, speaks in connection with Mr. Morris's sulphur and lime treatment of the mitigating effects of sulphurous gases upon the potato disease in the neighbourhood of certain copperworks. In a very clever paper which appeared in the *Ceylon Observer* lately, the partial immunity from coffee leaf disease of some districts in Java was explained by the presence of sulphurous vapors in the atmosphere produced by neighbouring volcanoes. Although the treatment of *Hemileia* has, with lime and sulphur, proved a failure practically, the idea of acting upon the fungus through sulphurous acid gas evolved by the contact of sulphur with lime—in short—of an atmospherical treatment remains correct. The fault of the treatment lay in the manner of application of the material direct to the plants, and of necessity, to the soil : its effects upon the fungus were too evanescent and the formation of sulphurous acid in appreciable quantities absorbed by the soil, disastrous to plant life.

The first instance of atmospherical treatment, I witnessed in the winter gardens and forcing houses of Germany, where earthen platters, partly filled with lime and sulphur were variously disposed all over the houses, and the practice answered very well under the shelter, and confinement of glass-roofs but how to adapt it to the open field was another matter.

Soon after the introduction of coffee leaf disease into this Colony, I had without any artificial aid, and only guided by the instincts of a gardener, made certain observations, followed by experiments, which convinced me that a thorough and lasting cure of leaf disease was possible. The first attempts I made were by direct applications, "dustings," with various substances, killing the spores as fast as they appeared on the principle of pulling a weed before it seeds ; by daily dustings with moderately caustic coral lime I succeeded in exhausting the spots of spores forming and ripening in the tissue of the leaves after about eight weeks. Of two Liberian trees treated in the same manner with sulphur and lime one died a slow death, whilst the other after being cured, was only saved by timely and careful transplanting into sweet soil. All the trees treated in this manner, with the exception of some which were reinfected afterwards through laborers from an adjoining district, remain clean to this day, twenty-three months

But direct treatment by hand, even if practicable and correct in principle, with bulky material such as lime, etc., must always be laborious and expensive, subject to interruption by the weather, and open to failure through careless performance. Besides these drawbacks such treatment must be comparatively valueless except on an estate, isolated or capable of isolation, because unless the treatment became general in a district or a province, infection would be re-imported from adjoining plantations as fast as the manual treatment could keep it under.

Whilst carrying on and making my observations on the above experiments I never lost sight of the practicability of a system of vaporisation adapted to the open field, and by degrees matured my "method of permanent vaporisation."

Carbolic acid in its quality of an antiseptic, has for a considerable time past been employed against various fungoid organisations, as also against *Hemileia Vastatrix,* but against the latter with only indifferent success, owing to the manner of application which in every case that has come to my knowledge to this date, was direct, manual, and therefore unreliable and expensive. My method is purely atmospherical, etc.

JACOB P. STORCK.

Belmont, Rewa River,
June 5th, 1882.

SERICULTURE.—The silk industry in the Mysore province some years ago provided occupation for thousands of people ; the export of raw material was large; there was a great demand for silk cloths from Mysore which were famed in the East and in Europe, and the revenue to the state from Sericulture was an item not to be despised. But bad times came, the worms were attacked with disease and died out, means were wanted to replace them, people grew disheartened and gradually from a very flourishing occupation, the silk industry almost became extinct. Recently, however, attempts were made in several parts of the province to revive silk manufactures, and within the past two years the cultivation of the mulberry for food for the silk worms has pushed aside in many places all other garden cultivation. We would, therefore, draw the attention of the Mysore Government to the necessity there exists of directing the endeavours of the cultivators into proper channels by which all possible risks of failure might be guarded against. The Agriculture Department of India have made arrangements for supplying such of the Local Governments and Administrations as are prepared to join in the experiment with small quantities of silk worm eggs of the univoltine variety for the purposes of silk-worm rearing. We surmise there is nothing to prevent an experiment of this kind being carried out in Mysore. But to do this properly the cultivation of mulberry should be extended and commenced at once in localities selected for trial. We believe the kind of mulberry found most suited for the ordinary silkworm is the *morus multicaulis* cuttings of which can also be had from the Agricultural Department. There are two kinds of mulberry cultivated in Mysore for silkworms—one indigenous, which is preferred by natives owing probably to its easy cultivation, the other an imported kind, which, though said to be the best, does not find favor with the native cultivators.—*Madras Mail.*

SEED-SOWING IN DRY WEATHER.

To obtain successions of many things, it is necessary to sow frequently. Though spring is the season for sowing the bulk of the main crops, yet in well-managed gardens, where every yard of land is made the most of, seed sowing must be a constant business; and if during a severe time of drought the seeds cannot be got in, or if they do not germinate, there is a break in the supply of that particular article. Take the case of any common vegetable in daily use, such as turnips or lettuces. The seeds will not grow in a dry dusty soil at this season; and yet it is important that both these crops should be sown now, more or less in proportion to the demand. The same thing occurs in the case of late peas. The season will soon be past for them, and in dry situations the seed may sometimes be in the land for days without making a move, simply because there is not sufficient moisture in the soil to induce germination. Ours is a porous soil, and at this season, even if there are flying showers, as there are now, we always like to well soak with liquid manure the drills for peas, French beans, turnips, radishes, endive, lettuces, and other things sown, for the next six weeks and draw the drills slightly deeper than would be necessary early in the season. Where there is no liquid manure tank, put a pound of guano, or two or three pounds of superphosphate, into a barrel of water, and a couple of pounds of salt. Stir the water well with an old brich broom, and well soak the drills; sow the seeds immediately, and cover with the dry soil drawn out of the drills. So treated, the young plants come up strong and vigorous, and get away from insect pests at once by their rapid growth. In some cases shade may be employed with great advantage. I found the simple expedient of hanging nets over a bed of turnips of great value in a twofold sense during the dry seasons we had ten or a dozen years ago; and these dry times may come back again.—E. H.—*Field.*

DR. BONAVIA'S HYBRID HIPPEASTRUMS.

In 1875, in the Lucknow Horticultural Garden, I had five or six kinds of ordinary Hippeastrums; one was a deep carmine, a second an expanded scarlet, a third a cream coloured one (probably H. Solandræflora); a fourth a curious small but firm petalled orange variety, with upright flowers; a fifth, a red one with bands on the middle of the petals, evidently a descendant from Amaryllis vittata, and another or two. I had them all in pots, in what is called a "chick" house—a house with walls and tops of reeds to keep out excessive heat and sunlight, and under which Ferns, Palms, &c., are successfully grown. With these materials, in April I began to cross promiscuously, to obtain as much Hippeastrum seed as I could. A large number seeded well. The seeds were sown as soon as ripe, and they germinated within a fortnight or twenty days. The bulbs were given more space every year, and eventually planted out in borders under the shade of shrubs and trees. They grew wonderfully, and about their third year many flowered, producing interesting varieties. These were crossed again among themselves, and with their parents, and the process of crossing and sowing went on annually; after the first time I showed the native head gardener how to manage it. These crossings and recrossings have now produced some marvellous results—both of form and colour—and something quite different from their original ancestors. Several of the most distinct have been lately named and catalogued.

Some marvellous forms and colourings have been produced from five or six of the most ordinary Hippeastrums, and taking those now in existence as a basis for future work, there is no telling what grand future is in store for the Lucknow hybrid Hippeastrums. They are cultivated in the open, and with the most ordinary care. They have taken to the soil and climate very kindly. Here are a few points which have been brought out during these experiments:—

1. I have in many cases tried them with their own pollen in order to endeavour to repeat in the seedlings the fine colouring of the parent, but have failed in every case. They appear not to be susceptible of fertilisation with their own pollen. Some of them set seed with foreign pollen with great ease, others do not.

2. It would appear that these Hippeastrums have Sprekelia blood in their composition, otherwise the form of A. formosissima in formosa and Dilkoosha is not easily accounted for.

3. There is often no knowing what form and colours may result from the mixing of the elements of two plants. It is like shaking their atoms in a kaleidoscope—every shake produces a new picture.

Truly, as Mr. Douglas says in the *Gardeners' Chronicle* of April 8, 1882, the Amaryllis has a great future. Some of the Lucknow strains crossed with the fine English ones might produce marvels of beauty. I gave up charge of the Lucknow Horticultural Garden in 1877, and the work of hybridisation is now carried on by my former assistants, Mr. Ridley, who is now superintendent, and Girdhari, the native head gardener. This is a Government garden, and is supported by the sale of produce and plants of all kinds. I have some of the Lucknow hybrid Hippeastrums, and intend making further experiments with them. —E. Bonavia, M.D., Civil Surgeon, Etawah, June 3, 1882.—*Gardeners' Chronicle.*

THE NATURAL HISTORY OF MADAGASCAR.*

Area and Physical Geography.—The island of Madagascar is exceeded in size by only two other islands, namely, Australia and Borneo. It is about 1,000 miles long, with an extreme width of 360, and an average width of more than 260 miles, which give an area of 250,000 square miles, or nearly four times that of England and Wales. It is separated from the east coast of Africa by a channel nearly 250 miles broad, and is situated almost entirely within the south tropical zone. A lofty granitic plateau, from 80 to 160 miles wide, and from 3,000 to 5,000 feet high, occupies its central portion, on which rise peaks and domes of basalt and granite to a height of nearly 9,000 feet; and there are also numerous extinct volcanic cones and craters. This mountain mass runs north and south, sloping steeply to the east, on which side are many of the numerous rivers, all of which flow through short, deeply cut gorges, making their way to the plain by a succession of wooded cataracts. The falls of the Matinana, for instance, leap at a single bound a depth of 500 or 600 feet. A good deal of this central elevated portion is bare and somewhat dreary-looking country, consisting of rolling moor-like hills, covered principally with long grass, which gets very dry and brown by the end of the summer. The soil generally is a red clay; and the highest level anywhere reached by the forest is 6,000 feet. In the Betsilo country there is some fine mountain scenery, and in the centre the Ankaratra Mountains rise to a height of 9,000 feet within a short distance of the capital, which itself is situated at a hight of 4,000 feet above the level of the sea. There are tracks of rich black alluvial soil in some of the valleys, where Rice, the staple food of the inhabitants, is cultivated. A belt of primæval forest runs all round the island, descending to the seashore in the north-east, opposite the French island of St. Marie. It is substantially continuous for a length of upwards of 2,000 miles, and the trees which compose it are imperfectly known. There is a vast extent of uninhabited country in the plains, where the soil is fertile, and there are wide tracts of land between the territory occupied by the different tribes in the hill country, as, for instance, what is called "No-man's Land," between Imerina and Betsileo, which are only peopled very thinly, or not at all. As scarcely any of it is desert, or rainless, it could doubtless support a large population, and there is probably nowhere else in the tropical zone such a wide extent of country so little interfered with, or where man has done less to modify the natural distribution of the plants and animals.

Climate.—Madagascar falls within the zone of regular periodical rains and winds; but there is no record of observations sufficient to give any precise idea of the climatal conditions of different parts of Madagascar, though enough is known to afford a general idea. In July, 1862, Dr. Meller made a trip from Tamatave, on the east coast, to Antananarivo, the capital, when the maximum shade temperature noted was 88° and the minimum 49°. The

* Chiefly compiled from an essay on the subject by J. G. Baker.

wet and warmer season lasts from November to April, when the monsoon wind blows from the north-west. At this time there is a heavy fall of rain, which sometimes continues incessantly for several days. The vegetation of the forests, the abundant epiphytes, the tree-mosses, the filmy Ferns, and the tendency in Ferns to viviparousness, furnish evidence of a humid climate. Dr. Parker, a resident in Madagascar, who has sent considerable collections of dried plants to Kew from the interior, writes to the effect that the flowering season of most plants in Madagascar, whether in the forest or out of it, is during the rainy season; but a very large majority do not commence till towards the end of December, whilst most of the grasses and sedges do not flower before the approach of the dry season.

Vegetation.—Turning again to Mr. Baker, he, in describing the general character of the flora, estimates that we have now definite knowledge of at least 2,000 species of flowering plants growing wild in Madagascar; and considering how many novelties each new parcel from an unexplored district contains, and what a large proportion of the named and described species gathered by the French collectors we do not possess in England, and how rich the Fern flora of the island, which has been much better explored than the flowering plants, he thinks the number of the latter inhabiting the island may be between 4,000 and 5,000.

The Vegetation of the Central Hill Country.—This is much better known than that of the forest belt or even the coast flora; and the endemic element is mainly specific. Its affinities are with the flora of the Cape and of the mountains of Central Africa. Mr. Baker summarises it in the following words:—"There are many curious cases of affinity between the flora of the hill-country of Central Madagascar and those of the Cape and the mountains of Central Africa. Many of the groups and genera characteristic of the Cape flora are represented in Central Madagascar, as they are in the mountains of Abyssinia, Angola, and Guinea, and the Zambesi country by species closely allied to, but not absolutely with those of their headquarters. At the Cape there are upwards of 500 Heaths; in Central Madagascar there are about a dozen species—one of Ericinella and the rest of Philippia. The Selagineæ are represented by a single endemic species, Selago muralis, which grows upon the walls of the royal palace in Antananarivo. The Aloes are represented in Madagascar by Aloe Sahundra and A. leptocaulon; the Cape Irideæ by species of Aristea, Geissorhiza,and Gladiolus; the Proteaceæ by Faurea and Dilobeia; the special Cape Ferns by Mohria caffrorum, Cheilanthes hirta, Pellæa Calomelanos, and P. hastata; the Cape saprophytic Scrophularineæ by Alectra melampyroides, and Harveya obtusifolia; and Cape Orchids by species of Disa and Satyrium; and the Cape Thymelaceæ by species of Dais and Lasiosiphon. Other characteristically Cape genera, represented by one or two endemic species in Central Madagascar are Phylica, Anthospermum, Diclis, Chironia, Halleria, and Streptocarpus. There are a few curious cases in which characteristically temperate species reach Central Madagascar, or a Madagascar species reappears at the Cape and amongst the Central African mountains. Among the vascular Cprytogams of Central Madagscar are Asplenium Trichomanes, Nephrodium Filix-mas, Aspidium aculeatum, Pteris aquilina and P. cretica, Lycopodium complanatum and L. clavatum; Asplenium Mannii reappears in the Cameroons and Zambesi-land. The only Madagascar Violet (Viola Zongia = V. eminensis = V. abyssinica) only occurs elsewhere at 7,000 feet above the sea-level in the Cameroons, at 10,000 feet above sea-level at Fernando Po, and in the mountains of Abyssinia. The only Madagascar Geranium (G. eminense = G. compar = G. simense, &c.) has the same range. The only Madagascar Drosera reappears at the Cape and in the mountains of Angola and Guinea. Agauria salicifolia, an Ericacea, is common to the mountains of Madagascar, Mauritius, Bourbon, and the Cameroons; and has lately been found on the high plateaux round Lake Nyassa. Caucalis melantha occurs only in Central Madagascar; in Abyssinia at an elevation of 9,000 feet; in the Cameroons at 7,000—8,000 feet; at Fernando at 7,000 feet." From the foregoing extract it will be seen that there is a distinct affinity between the mountain floras of Madagascar and the continent of Africa.—*Gardeners' Chronicle.*

STRAWBERRY CULTURE.

Strawberry plants are now generally grown in lines, at a distance of some 3 feet from each other, and at about half that distance from plant to plant. They will succeed in any ordinary good soil, but prefer one of a light, rich, loamy character, which should be trenched or deeply dug, and at the same time sufficiently enriched with manurial matters to sustain the plants for at least two years. The Strawberry may, of course, be increased by seed, and it is only by this means that new and improved varieties can be secured.

The usual mode of increase, however, is accomplished by the runners which spring from the stock of the old plants, their use being that of transporting the young plant to some distance from the stock, and to fresh soil, on which it is not slow to establish itself; and thus, as the old plants become worn out, and ultimately die, their place is taken by runners, or young plants, and extinction is for a time thus prevented. In order to obtain young plants for the formation of new plantations, as well as for the purpose of forcing, the soil between lines of established plants should, about the middle of the month of May, be loosened or forked up, and a line of 3-inch pots, filled with rich, light soil, should be sunk in the same to the level of their rims, and in the centre of each pot the joint of a runner should be placed, and this should be kept in position by a small peg, or even by placing a small stone upon it. The young plant will soon root freely into the fresh soil, and if the weather following this operation prove dry, the pots should be freely watered every evening, and as the primary object in view is to obtain strong young plants at as early a period at the season as possible, the young plants need not be severed from the parent plants until the small pots they are in are well filled with roots; and soon after this has been done, the weather and the soil being in proper condition, the plants intended to form a new plantation should be at once carefully planted out, while those intended for forcing should be transferred to their fruiting pots, which need not exceed 6 inches in dimeter. The operation of planting out, as well as that of re-potting, should be performed in such a way as to avoid giving anything like a check to the plants, and should if possible be accomplished before the month of June has ended; while during the remainder of the summer the plants should have every necessary attention, in the way of watering, keeping clean, &c., and unless she season proves exceedingly unfavourable the planted-out plants, as well as those in pots, will generally be found strong enough to carry fair crops of the finest fruit—those planted-out in the open air at the usual season, in the following year, while the fruit of the plants in pots will ripen in accordance with the time they are started into growth. And these forced plants, if planted-out after the first crop of fruit has been gathered, will seldom fail to produce a most abundant crop in the season following. The produce of the planted-out plants will also be more abundant in the second season than in that of the first, although the individual fruits may be less fine. And such plantations may, if desired, be retained for any number of years, but the crops, as well as the quality of the fruit, will generally be found to detriorate after the second season. In the forcing of the Strawberry plant it is of great importance to place the plants as near as possible to the glass, and to commence with a comparatively low temperature, which should of course be gradually increased as the season advances, and as the plants develope themselves. But, as a rule, the night temperature should not exceed 60° until the fruit has fairly set, nor should the day temperature be allowed to exceed 70° without air being admitted to the structure.

Some varieties of the Strawberry, more than others, are apt to produce unisexual flowers, which does not, however, prevent the production of fruit; in order, however, to prevent the same being defective or deformed in any way, or to prevent blooms running altogether "blind," as it is called, more particularly during early forcing, it is advisable to take advantage of fine days, or during intervals of sunshine, to distribute the pollen with a small brush or camelhair pencil. When the fruit is fairly set, it may be found necessary to more or less thin it out, and in doing this all small or imperfectly formed fruits should be removed, and this will tend to

render the remainder more fine; and as soon as this begins to colour or to approach a ripening condition, the trusses should be raised on twigs or small branches of any kind, or even neatly staked and tied up, so as to keep the fruit clean, by removing it from the surface of the soil, and to allow the air to circulate freely among the ripening berries. This gives also an attractive appearance to the plants, and is better than allowing the fruit to hang round the sides of the pots and in contact with them. Some have objected to this practice, contending that the natural position of the fruit of the Strawberry plant is upon the surface of the soil. There can, however, be little wrong in assisting or even improving upon Nature in this respect, and a Strawberry plant growing in a pot is, of course, in an artifical condition. It is also equally necessary to prevent the fruit of plants growing in the open air from resting upon the surface of the soil, which, if allowed to do so, however fine it may be, it is nevertheless almost sure to be rendered useless by having the grit from the soil washed upon it by heavy falls of rain. Various means have been resorted to as a remedy for this evil. What are known as Strawberry tiles have been invented and highly recommended, but from some cause (possibly their expense) they do not appear to have ever come into general use. The raising of the tursses of fruit from the surface of the soil upon twigs or small branches has also been suggested, and to some extent practised. But it increases the temptation which ripe fruit presents to the blackbird, &c., it also involves considerable trouble, and can hardly be recommended. Tanner's bark in the neighbourhood of towns or where this material can be readily obtained is very frequently used, with the desired effect for the purpose of mulching the surface of the soil and preventing the same being washed upon the fruit. It has also the very desirable property of driving away slugs, snails, woodlice, and other troublesome pests, which are always sure to attack ripe fruit, clean straw of any kind may also be effectually used for the purpose; indeed it is quite possible that from the use of this material in early times, that this delicious fruit may have derived its designation of the straw berry. Another material, which is perhaps more extensively used for the purpose than any other, although by no means free from objections, but in most garden establishments it comes to hand readily, and is certainly not unsuited to the purpose in view—this is the short grass, or the mowings of the lawns, &c. But weather tiles, straw, or grass be used for the purpose, the soil between the lines of plants should previously have a good dressing of soot, gas lime, or even a slight sprinkling of salt, as any of these will have the effect of keeping away most of the insect pests which have been alluded to until such time, at least, as the fruit has been secured. But in addition to all that has been recommended, it will be necessary in country places, or wherever birds are prevalent, to protect the Strawberry plantations with nets, or wirework, as soon as the fruit approaches to a ripe condition.—P. GRIEVE, Bury St. Edmunds.—*Gardeners' Chronicle.*

MANURES AS ABSORBENTS OF WATER.

BY A. STEPHEN WILSON.

(*Continued from page* 268.)

FOURTH SERIES.

The fourth series of comparisons consisted of some of the same manures as were used in the third series. They were taken from the same dried heaps, but put into cups of a different form, the intention being to have confirmation of results under various circumstances. The cups were placed in the same floor upon a board, so as to avoid adhesive moisture.

In this experiment the cups were deeper and had less surface than in the previous case, but the order of absorptive power is nearly the same as before. The period of exposure was the same as in the third series, but the Potato manure—the most powerfully absorptive of the set—has here only taken up 59 per cent, while in the previous case it took up 92 per cent. Probably the difference is to be explained partly by the difference in area of surface exposed; but there are evidently other consideration involved, because in this case the deeper cup of cow-dung with less surface has the higher weight of absorbed moisture, namely, 19 as against 16. I shall not at present attempt to explain this difficulty, as it in no way affects the main contention.

FIFTH SERIES.

The fifth series of comparisons was also with some of the same manures as above, dried in the same way, but tested in another form of cups, and in the same place as the others.

Here the coprolite dissolved with sulphuric acid absorbs four times as much water as the same coprolite merely ground to a fine flour. In the third series the dissolved phosphate took up five times as much as the ground phosphate. The difference no doubt arises from causes acting in relation to difference of surface exposed; but that the superphosphate absorbs a large amount of moisture more than the ground phosphate is clear. It is clear also that the guano, as compared with the soil and the ground phosphate, has a high hygrosorptive power.

DEDUCTIONS.

No new property in any of the substances here experimented with is assumed to be discovered; but only some of the well known properties assumed to be set perhaps in a new light. Into the composition of guano, superphosphate, and the various Turnip and Potato manures, enter large quantities of various salt of a highly deliquescent character—that is, salts which are highly hygrosorptive. The large percentages of sulphate of potash and ammonia in Potato and Turnip manures, explain why, in the above experiments, these manures absorb such large quantities of moisture. A comparison of the composition of the superphosphates with the undissolved materials of which they are formed, also explains why these materials, after being treated with sulphuric acid, became more absorptive of moisture.

Now if in a dry season part of a Turnip crop, for example, is laid down with a hygrosorptive manure and part with a non-hygrosorptive, the plants in the first case will be better supplied with water than in the second case.

HOW ROOTS GET WATER.

But how do the roots of plants get water? In plants which grow in water in its liquid from, the roots are directly in contact with water, and the matter seems plain. But with plants which grow in drained land, where there is no water in a liquid from, the aspect of things is different.

I filled pots of clear glass with small stones and loose open soil up to near the brim and finished with a thin layer of good soil. Seeds of Oats, Wheat, and Barley were then planted close round the edge, so that their roots would come down near the clear glass though and amongst the openings made by the small stones and lumpy soil. Whenever a fresh growing root appeared in an available position, a low power objective was directed upon it, and it was found that the root-hairs were covered with innumerable vesicles of moisture. I therefore concluded that in dry soils the roots of plants do not go in search of water—the water comes in search of them. The water which they need is condensed upon their root-hairs, and thence absorbed into the tissue.

Now a manure which has a highly hygrosorptive capacity will keep the soil around the roots of plants better charged with moisture than a manure of the opposite character; evaporation will fill the interspaces of the soil with vapour, and will thus enable the moisture withdrawn from the air to be condensed on the roots. Whether any part of the food of a plant may be condensed in soultion upon the root-hairs in addition to mere water may be a question. "Liebig has suggested," say Johnston and Cameron, "that plants do not take up their food in solution, seeing that it is so sparingly soluble in the liquid present in the soil. It seems, however, improbable," they add, "that solid matters could pass into the organisms of plants, and we can hardly accept Liebig's theory, at least in its entirety, until our knowledge of the physical condition in which the food of plants exists in the soil is considerably enlarged" (pp. 229, 230, 11th ed.). The "solution" implied by Liebig was solution in liquid water. But if any part of plant food—ammonia, for example—may be vaporised and condensed within the vesicles on the roots, a different view is opened up.

Certain manures are characterised by giving a rapid growth to plants in the early part of the season. Two main causes combine to render hygrosorptive manures rapid in their action; they are soluble, and they have the capacity of absorbing the moisture which renders them fluid, thus distributing their particles and rendering them highly available by the roots.

Hygrosorption in Relation to Fungi.

But other incidental consequences will arise from the hygrosorptive action of a manure. From certain experiments made by Mr. Thomas Jamieson, he has discovered that manures treated with sulphuric acid have a greater tendency to foster the development of club-root in Turnips then manures not so treated. His explanation is that the sulphur in the manure and in the Turnip is the predisposing cause of clubbing (see Report Aberdeen Agr. Assoc. 1880). This explanation does not seem to me to meet the requirements of the case. M. Woronin has clearly shown that the cause of clubbing in the roots of Brassicaceous plants is the simple spore-bearing parasitic fungus which he names Plasmodiophora brassicæ His main conclusions have been all verified by the present writer. Now the spores of this fungus, which are minute hyaline spheres, lie quiescent through the winter. In the early summer, if they are supplied with moisture, they give off zoospores, which very soon "plasmodiate" or become fused together into a homogeneous, semi-liquid mass. A manure, therefore, of a hygrosorptive character, is just the very manure to promote the plasmodiation of these spores, and render them fit to be absorbed in the form of a fluid plasm by the roots of the plants. We do not directly know that sulphur promotes the germination of this fungus, but we do know that the moisture accompanying a manure dissolved by sulphuric acid is a *vera causa* in promoting the germination of the spores of this fungus; in other words, the application of moisture to a spore previously kept dry is directly seen to cause it either to give birth to a zoospore or to plasmodiate retaining its contents—both results being essentially the same, and giving rise to a speck of granular plasm. But upon this view any manure of a highly hygrosorptive character, whether containing sulphur or not, should be found promoting club-root. This, accrodingly, is known to be the case. Land manured with sea-weeds, the salts forming which are highly absorptive of moisture, has had to be disused as a Turnip soil—owing to the prevalence of clubbing. But, indeed, all the manures here tested are more or less hygrosorptive as compared with soil; and all manures are occasionally found associated with clubbing. The enormous clubbing of the Cabbage roots in the market gardens around St. Petersburg, referred to by M. Woronin, was not caused by the use of superphosphate. And the first recorded prevalence of this disease is found by that botanist in the writings of a Spanish king of a date earlier than the invention of dissolving manures with vitriol. Besides this fungus attacks the stock Gilliflower, and other plants which never receive dissolved manures. In corn-fields where no superphosphate has been applied, the Charlock is in many cases found to be clubbed. And the fact that clubbing in Turnips goes along with superphosphate, or along with manures containing deliquescent salts, finds its natural explanation as a corollary of the theory of hygrosorption. The manures do not cause the club-root fungus any more than they cause the plants in which it grows—they simply promote the growth of both; and the more rapidly the host-plant grows, or multiplies its cells, the further through its tissues will the plasm of the parasite be carried.

The Potato manure in the above tables contains a high percentage of potash, and is the most hygrosorptive of the set. There can be no doubt, therefore, that the growth of the non-parasitic system of the Peronospora infestans, or Potato fungus, will be promoted by such hygrosorptive manures. The parasitic system of this fungus, as it exists in the Potato leaf, grows mostly during the night, when plenty of moisture is available; and the non-parasitic mycelium, arising from conidia and resting spores within the soil, can only grow and extend its lines when surrounded by a moist medium.

The manures here experimented with only began to promote the germination of certain moulds after the salts had been so far diluted by the water they absorbed as to be harmless to the fungi; for it is obvious that strong sulphuric or other acid would be destructive to all vegetable life. But if manures are favourable to the growth of phænogamous plants, all the more likely is it that they will be favourable to the growth of cryptogamous plants. Indeed hardly a speck of decomposing or rotting matter, in other words manure, can be found free of certain parts of some non-parasitic fungus. And if manures, which are simply plant-food, are thus favourable to non-parasitic fungi of all kinds, they must be favourable to the non-parasitic elements of those fungi which attain their perfect or fruit-bearing condition as parasitics in the tissues of phænogamous plants. And that the hygrosorptive action of manures should favour the growth of certain Cryptogams is no more to be wondered at than that the same action should favour the growth of certain Phænogams.

But these effects on fungi are rather to be regarded here as incidental. The direct value of hygrosorption in a manure is the supply which it draws of moisture from the air for the roots of plants. The manure requires to be so nearly in a liquid form, as that it may find its way osmotically through the cell-walls of the roots, and it has the property of being able to absorb from the air the very moisture required to liquify it. The process is still further accelerated by the condensation of vesicles of moisture upon the young and growing fibres of the roots. It is not water in the liquid form which agricultural plants require, but water in the form of condensable vapour, and this is what is partly supplied to them by the hygrosorption of manures.

In their ordinary market condition these manures usually contain from 12 to 15 per cent of moisture. But we see that they can add largely to this amount when exposed to the atmosphere. And the more powerfully a manure abstracts moisture from the air the more powerfully will it resist drying or the giving of it up again. During the night moisture will be drawn from the air, and during the day a part of this moisture, vaporised within the soil from the dead material of the manure, will be condensed upon the living roots and root-hairs in the form of minute dewdrops to water the plants. Farmyard manure, which keeps the soil open, has a mechanical value in creating air-chambers, from which vapour may be condensed upon the roots passing through them, succeeded by a chemical value consequent upon complete decomposition.

By what cause moisture is thus condensed upon the root-hairs is doubtful. My own experimets with masses of the young roots of Cress and Turnip growing through little wire baskets under a water-closed glass bell, and having a delicate thermometer which could be brought into contact with the roots, gave no decided indication that the roots were colder or warmer than the surrounding air. Other trials made within the soil were not satisfactory. The matter deserves further investigation, and will probably brining into view some new facts regarding the relationship of plants and their food; and also some new facts in explanation of the theory of drainage.—*Gardeners' Chronicle.*

SUBSTITUTES FOR CINCHONA BARK AND OTHER PRODUCTS.

(*Pharmaceutical Society Meeting, April* 1882.)

Mr. Holmes, Curator of the Museum, called attention to various specimens on the table. He first referred to some herbarium specimens of different forms of the Japanese aconite plant, lent by Professor Maximowicz and gathered by him in Japan. He (Mr. Holmes) had received a specimen direct from Japan through Professor Kinch, as being the plant which yielded the Japanese aconite of commerce; but feeling some doubt about its identity, on account of its roots being more tapering than those usually met with, he had sent a leaf of the plant to Professor Maximowicz, asking whether he could tell if it was from *Aconitum Fischeri* or not. He had received the following letter in reply:—

"Your aconite leaf seems to me to belong to *A. Fischeri*, itself a very polymorphous species as to its leaves and size, but sufficiently different from *A. Napellus* by its flowers. There is much doubt yet what is to be considered a good species in *Aconitum*, the forms being extremely numerous, but running into each other to an extent which is perfectly puzzling. But *A. Fischeri* can be held as a species, it seems."

One of the specimens lent by Professor Maximowicz had a root which tapered suddenly at the apex, and in that particular it seemed to differ from the ordinary aconite of commerce, which tapered gradually down to a point. One of the specimens of Japanese aconite sent by Professor Maximowicz had a root nearly approaching to that of *A. Napellus*, but the foliage was very different. It would be seen, from the specimens on the table, that *A. Fischeri* was a very polymorphic plant and one very variable in character. There were also some specimens of the valerians which grew in Japan, which he had borrowed from Professor Maximowicz, being desirous of ascertaining what species yielded the Japanese valerian root exhibited at a former meeting. None of these borrowed specimens, however, seemed to have roots identical in character with the Kesso or Japanese drug, and therefore he presumed that the latter was obtained from a different plant. There were two specimens of aconite root presented by Mr. Squire, one being from *Aconitum paniculatum*, and the other from *Aconitum Napellus*. They approximated very closely in appearance and general character. It was not surprising that growers were puzzled in distinguishing the different varieties which were met with in gardens or obtained from the florist. The best practical test for distinguishing these two species would appear to be in the absence of tingling in the taste. Mr. Squire had also sent a root of biennial henbane, which, he maintained, could be grown as an article of commerce. The present specimen was grown from seed sown in March, the root being dug up in the March of the following year. There were also some specimens of bark from Jamaica, from Mr. D. Morris, Director of the Botanical Gardens of Jamaica, who kindly sent specimens of drugs which came under his notice. One of the samples of bark was a very bitter one. The Director had written, saying—

"I send you a few scraps of a bark sent me the other day from Hayti as a 'cinchona.' It has a remarkably warm sweetish bitter taste, and I am inclined to think it might be useful as a tonic or stomachic. Unfortunately I could get no account of its source beyond being 'the bark of a tree common in Hayti.' If some friend of yours would care to analyse it, the result might be interesting. I am endeavouring to get further particulars so as, if possible, to identify the tree from which it is obtained, but I cannot promise much in this way as Hayti is a most difficult place to get anything from."

He (Mr. Holmes) had compared this bark with specimens already in the Museum, and it seemed to be exactly identical with an *Exostemma* bark, which was used in Hayti and several other islands of the West Indies as a bitter tonic. Some specimens had been presented to the Museum by Mr. E. G. Schweitzer, one of these being a very pretty one of the alpha resin of copaiba, which had been described by Berzelius. He (Mr Holmes) believed that it was obtained by digesting the resin in ammonia, and allowing the ammonia to evaporate. Another specimen presented by him was columbin, the bitter principle of columba root. The Museum was by no means rich in specimens of the active principles of plants which were discovered in the early part of the century. This one, which was discovered by Wittstock in 1830, was one of the few which had been presented to the Museum. Probably there were in private laboratories many interesting objects of that kind, and these would be gladly received by the Society for the purpose of illustrating the active principles of various drugs. Mr. T. Christy had presented an article which was very rarely seen in this country, namely, the pod of the tonka bean. The seeds in the pod were sufficiently fresh to grow. Another specimen from the same donor was pure papayotin, the active principle of the papaw, which had been prepared in Jamaica. This substance was a very interesting one, as it had lately been shown that pepsine, like this substance, formed an insoluble compound with fibrine which underwent hydration. Hence the resemblance between papayotin and pepsine was much greater than had been imagined.

The President remarked that anything in connection with medicinal plants contributed by Mr. Squire was entitled to great consideration. Mr. Squire grew several, and he was exceedingly careful and very observant respecting them. Mr. Squire had mentioned to him (the President) that he intended sending to the Museum these two roots, *Aconitum paniculatum* and *Aconitum Napellus*, which had been grown on his own grounds. He had supplied him (the President) with a root of each, which had been in spirit for some time, and also gave him a sketchy drawing of each. As Mr. Holmes had said, from the drawing it would be extremely difficult to distinguish for practical purposes between the two varieties. But in making sections of the two roots he (the President) had found a very great difference between the two, so that there was not much difficulty in determining which was "paniculatum" and which was "napellus." Curiously the section of the "paniculatum" closely corresponded to a section of German aconite. It seemed likely, therefore, that roots of *Aconitum paniculatum* were very often mixed with the roots of *Aconitum Napellus* imported into this country from Germany. He thought that the German aconite sent here generally came from the neighbourhood of Prague in Bohemia. He believed that it was gathered by men who went out into the range of mountains running from Bohemia to Salzburg, and gathered medicinal roots of several kinds, and then took the roots in a bag and sold them to pharmacists, leaving the purchasers to distinguish which was gentian and which was aconite. Bearing in mind that in the roots of *Aconitum paniculatum* there was an absence of the tingling property, it was of some importance to determine accurately whether a large proportion of this root came over mixed with the German roots of professedly *Aconitum Napellus*. The two or three sections which he had made of one part of the root of each of these two varieties scarcely enabled him to express a positive opinion with regard to the character of the sections being uniform throughout the root. It was very possible that the section might differ in different parts of the root. It would be necessary to take sections from different parts of the roots and from many roots to be able to determine whether there was any difference of section which could be relied upon between *Aconitum paniculatum* and *Aconitum Napellus*. He might remark with regard to the specimens from Mr. Maximowicz, that he met him in St. Petersburg two years ago, and sketched on a paper a Japan aconite root of which he had been able to make sections. Mr. Maximowicz immediately said, "That is *Aconitum Fischeri*." He seemed to be very well acquainted with the aconites as grown in Japan. But the history of the aconite roots and the varieties imported seemed to be involved in mystery.

Mr. Postans mentioned a circumstance which occurred recently in connection with hyoscyamus. He had always used the leaves of the biennial variety of *Hyoscyamus niger*, but he ordered a fresh supply in, and after a while some of it was made into tincture. This was a nice-looking preparation, although a much brighter green colour than the B.P.; when mixed with water it presented a different appearance from that of the biennial plant. He was told that a considerable quantity of annual henbane was in the market, and that it was sold largely in some districts for the preparation of tincture of hyoscyamus, principally because of its cheapness. The British Pharmacopœia recognized only the biennial plant, and the annual henbane of which he had spoken was evidently a different variety of the same species; it would seem important, therefore, that pharmacists should know whether comparative experiments had been made as to the usefulness of the two sorts.

Mr. Cleaver said that it had been several times stated that the annual and the biennial henbane varied very little with regard to the percentage of hyoscyamine to be obtained from them; but there was a much more powerful smell from the biennial than from the annual; and biennial precipitated with water. This would tend to show that there was something besides hyoscyamine in the biennial which gave the remedial properties to the tincture of that variety. As to the specimen of root of henbane on the table, it certainly seemed remarkable that they had never had any use of it in pharmacy. Considering the comparatively large development of root, it would be useful if something could be done with it. He should like to know whether a chemical examination of it had been made. With regard to the aconite specimens, it was well known that the Japanese aconite contained a large quantity of alkaloid. There appeared to be something very peculiar in the climate of Japan, for the Japanese valerian root was very much more powerful than the English, as regarded the volatile oil in it. And in the case of peppermint, the quantity of oil of peppermint

yielded by the Japanese plant was considerably more than that yielded by the English plant, and of a very different odour.

Mr. Holmes said that the difference between different varieties of plants was very important. An instance in point was the Japanese peppermint oil, which he had alluded to, and which was obtained, not from *Mentha Piperita* but from a variety of *Mentha arvensis*, which in England yielded an essential oil that was quite different in taste and odour. Botanists observed but very little difference between the English *Mentha arvensis* and the variety used in Japan for peppermint oil. In the same way, botanists had classed together a great many aconites in the same group as *Aconitum paniculatum*, some of which were known to be poisonous, although that species did not appear to be so. It seemed to him that the aconites required examination from a chemical as well as a botanical point of view. A chemical examination might throw considerable light on the botanical relationships of different species which were now classed together. He observed that the Pharmacopœia said concerning aconite root "Imported from Germany or cultivated in Britain." He thought that it would be highly important in the next Pharmacopœia to omit the words "Imported from Germany," because, until they could be sure that all the German aconite was obtained from *Aconitum Napellus*, they would frequently get varieties of which they knew nothing, and consequently it would be impossible to say whether German aconite contained aconitine in various proportions or some other alkaloid, which might not possess the same properties as aconitine. The specimen of henbane root referred to by Mr. Cleaver was the only one received from Mr. Squire, and it had not been examined.

The President said that he believed that the only mode of determining whether a tincture of hyoscyamus had been made from the biennial henbane or not was the use of the spectroscope, as was pointed out by Mr. Stoddart some years ago. At the Swansea Conference, he (the President) had read a note on some henbane from India, and Mr. Umney then made the remark that on the continent hyoscyamine was prepared from the annual henbane.

Dr. Symes, on behalf of Mr. Williams, who was absent in consequence of ill-health, brought before the meeting some observations on chinoline. He said that this was a body which was exciting attention in the medical world, and therefore had an interest for pharmacists. Mr. Williams had sent some very nice specimens of chinoline, pure and tartrate, artificial and otherwise. Chinoline had the chemical formula of C_9H_7N. It was prepared originally some few years ago from cinchonine and quinine, and was said to be also prepared from strychnine. Cinchonine was, however, its principal source, and it was prepared by heating that alkaloid in a solution of caustic soda. In fact, the cinchonine underwent destructive distillation at a high temperature, the result being a very dark red oily-looking liquid, which had a most unpleasant odour, and was very impure. Professor Greville Williams devoted considerable attention to this body. Upon being redistilled, it produced a brownish liquid, which was still impure, and a tarlike residue. Professor Greville Williams found five or six other basic bodies present in this liquid, in addition to chinoline. He came to the conclusion that the best means of obtaining pure chinoline was to produce the chromate. Latterly, however, chinoline had been produced synthetically, and it was this fact, probably, which had caused some amount of inquiry into its nature. The original use to which this body, as prepared from cinchonine, was devoted was the production of cyanine, a blue colouring matter, by heating it with iodide of amyl and potash. Chinoline was produced synthetically by the action of caustic potash upon a mixture of glycerine and aniline. He did not know that there was any published description of the method; but he believed that it was patented in Germany and possibly so in England. The Germans found that the best means of obtaining pure chinoline was by the production of a tartrate. They found that on treating the chinoline with an excess of tartaric acid and boiling water, the chinoline tartrate crystallized out, and many of the impurities were separated in the mother liquor. The present specimen had been obtained by forming an acid tartrate in boiling water, and allowing it to cool and crystallize in this way. The process had been repeated three times to obtain a comparatively pure salt. When it was wished to obtain a pure chinoline, the tartrate was decomposed with caustic soda and agitated with benzine. This was the method of purification which had been adopted by Mr. Williams himself. The benzine dissolved out the pure chinoline, and left behind some trace of impurity which still existed in the tartrate. The solution in benzine was then evaporated until the smell of benzine had disappeared. The liquid was then distilled, and about an eighth or a ninth of the liquid came over at a temperature below 238° C. That was not pure chinoline, but the pure chinoline would distil at that temperature. There was a specimen of it present, from which it would be seen to be an oil-like liquid having a pale brownish tint. The artificial had very much the same appearance. From chinoline (as had been stated) cyanine had been prepared, by treating the chinoline with iodide of amyl. The blue colour was developed on the addition of caustic soda. If some chinoline were put into a test tube and held over the flame of a spirit lamp, it darkened after a time, and ultimately formed a red resinous body; the addition of caustic soda then developed the blue colour. The artificial chinoline treated in this way yielded a brownish and not a blue colour. Mr. Williams particularly wished him to say that he did not put this forward as any evidence of impurity in the artificial chinoline. Although chemically the same as the natural chinoline, it would appear as though there must be some different arrangement of the molecules, or difference in the physical constitution. It was known that leucoline, having the same chemical formula as chinoline and obtained from coal tar, does not yield cyanine. The tartrate of chinoline was the substance which was used internally for medicinal purposes. It was supposed to be a cheap substitute for quinine, but its taste was rather unpleasant. He was not prepared to say how far it fulfilled this purpose medicinally. He had been informed that the pure chinoline had been used for the purpose of producing local anæsthesia.

Mr. Passmore, in reply to Dr. Symes's query, said that a description of the process for the synthetic preparation of chinoline had been published by Herr Skraup in the Austrian *Monatshefte fur Chemie* about twelve months previously. Herr Skraup preferred to act with an alkali upon a mixture of nitrobenzine and aniline in the presence of glycerine, for although either nitrobenzine or aniline would yield chinoline, the one by the elimination of hydrogen, and the other of oxygen, the yield from a mixture of the two appeared to be more favourable. From the description of the process he should gather that very great difficulty was experienced in the purification of the product, the chinoline being produced in a mixture of similar bodies, rather than as a definite body in a state approximating to purity.

Mr. Robbins said that he was with Dr. Symes when Mr. Williams explained the process to him, and they might congratulate Dr. Symes on the very lucid way in which he had made the communication. Mr. Williams had been prepared to perform the experiments necessary for illustrating the process, and a number of other experiments of an interesting character. He (Mr. Robbins) thought that this was one of the most interesting subjects which had been before these meetings for some time. It was a curious fact that the artificial chinoline was not exactly the same as the natural, for, although they were unable to distinguish the two kinds in many ways, still the artificial would not yield cyanine. This showed that there was a difference in the arrangement of the elements. As to the use of chinoline as a medicine, it was a nice-looking white crystalline body, to the appearance of which no one would object, but its taste was so excessively disagreeable, that it must have many advantages which quinine did not possess, if it was to supersede that drug. The taste of quinine, although bitter, was yet pleasant in comparison.

Mr. Carteighe said that several of the specimens of chinoline which he had examined, though not in a very detailed way, had given him much the same impression as that recorded by Mr. Ekin in a short note in the Journal a few weeks ago. Because chinoline was produced artificially in a cheap way and possessed certain crystalline characters, and was regarded in the report of

one or two persons to be a substitute for quinine, it did not necessarily follow that further investigation would show that it possessed all the virtues ascribed to it. There were two or three distinct varieties of the artificial substance and its salts in the market. He had compared these with some specimens which were made many years ago, when Greville Williams first discovered the compound, and he must say that he had found there was a very material difference between them. The fact that this was the case should be a warning to pharmacists not to use these products indiscriminately. The very strong way in which the importers of the salts of chinoline spoke of their medicinal properties ought to be a caution to pharmacists to be careful in dispensing them.

Mr. Holmes said that Mr. Williams showed him in his laboratory the experiment for producing the blue colour from chinoline, and he succeeded in obtaining the colour to perfection. The cyanine fell down as a resinous substance with a a coppery lustre like that of indigo when rubbed. In treating artificial chinoline in the same way, he obtained only a pale red colour which was perfectly different from the colour produced from the natural body. It would appear, therefore, that Greville Williams's chinoline was not the kind which was used in Germany. The one with which the therapeutic experiments had been made appeared to be the German article. Whether the latter was compound or a pure body he could not say, but it appeared to him doubtful whether the chinoline obtained from cinchonine had the same properties as the one which Dr. Donath had described. It was an important question to be decided for medical men and chemists: whether artificial or natural preparations should be used. Many medical men who did not closely observe the journals might not be aware that there was any difference in physiological action between what were called the natural and the artificial preparations.

Mr. Walter Hills said that when an article like chinoline was on its trial it was very important that the kind originally introduced should be used. The same remark applied to salicylate of soda, concerning which they had heard that the artificial compounds had given rise to certain disadvantages which might have tended to rather lower those bodies in the estimation of those who prescribed them. It was shown that there was some physical difference between the artificial and the natural chinoline, and possibly there was some medicinal difference also.

Mr. Carteighe said that it was obvious that the formation of an alkaloid or any distinct organic body synthetically in the proportion of 95 per cent was a matter of very great interest chemically, but it was a question how far such a substance might be useful in medicine with a small amount of impurity, which it was difficult to remove. The production of bodies of this class on a cheap scale was a matter to be encouraged by pharmacists, if the artificial preparations had the requisite therapeutic properties. Many pharmacists would submit to a great deal of personal torture to introduce them; but they must know what they were experimenting with, and must be assured that the process of "vivisection" to which they submitted would advance therapeutics. They could not make statements as to the value of a preparation when after all it was more or less an impure product, and that appeared to be the condition in which all the salts of chinoline were presented.

Mr. Cleaver suggested that the chinoline appeared to be called a substitute for quinine, merely on account of its possessing febrifugal properties or reducing the temperature of the body. If so, there were plenty of nicer things which would do as well.

Mr. Postans said that the opinions which had been expressed about chinoline quite coincided with his own. The discussion raised the all-important question of the ethics of isomers, for hardly two chemists were agreed on this subject. That being so, it was extremely difficult for pharmacists to take unartificial preparations if they could possibly procure natural ones. If two bodies possessed an isomeric composition, how was it that they presented different appearances, and that as experiments were made by competent men from time to time certain differences were discovered which years before had not been found. They were told that this was due to a "re-arrangement of the molecules," but it was curious that this re-arrangement did not take place in the same way in natural products, and he could not help thinking that the artificial products were like the objects in Madame Tussaud's exhibition. There was everything there most beautifully prepared to represent life, but there was not life.

The President said that he had tasted the artificial chinoline, and he thought that it would take a person a very long time to get fond of it. He thought that it would be difficult for a delicate stomach to tolerate it.

This being the last meeting of the session, on the motion of Mr. Robbins, a vote of thanks was cordially awarded to the President.—*Pharmaceutical Journal.*

THE AUSTRALIAN TEA SEASON: 1882-83.

Melbourne, 1st July 1882.

The Calcutta Tea Syndicate, in conjunction with the Government of India, will carry on their operations during season 1882-83.

The favour with which Indian Teas have been received during the season just closed, has been most gratifying to the concerned, and whilst regretting that the supply sent forward to the Colonies has not been found equal to the demand, hope to obviate this drawback by increased supplies during the current season.

All teas passing through the hands of the Syndicate are carefully selected and examined prior to shipment from India. Further, on arrival in Melbourne, the bulk of every line of tea will be submitted for inspection and analysis, and a warrantry given with full particulars of such analysis, and on every catalogue issued, if time before sale permits of this. But in all cases the Syndicate guarantee all their teas as pure and free from any adulteration.

India, with her tea gardens at altitudes of from 400 to 7,000 feet above the sea-level, her climate and rich soil possesses advantages unequalled in the world. Her teas are prepared under the immediate supervision of Europeans, and with the help of the finest machinery procurable, many of the Indian tea-growths are as much in repute as some of the far-famed vintages of the Continent.

The crops of Indian tea during the past 10 years have been as follows:—

1872	17,900,000			
1873	19,750,000	Increase	1,850,000 or	10·33 per cent.
1874	23,300,000	„	3,550,000 or	17·97 „
1875	26,100,000	„	2,800,000 or	12·02 „
1876	29,400,000	„	3,300,000 or	12·64 „
1877	35,800,000	„	6,400,000 or	21·77 „
1878	35,000,000	Decrease	800,000 or	2·23 „
1879	40,000,000	Increase	5,000,000 or	14·29 „
1880	46,500,000	„	5,500,000 or	13·75 „
1881	48,300,000	„	1,800,000 or	3·83 „
Total increase in ten years			30,400,000 or	170 per cent.

and if the 1882 estimate of 51,619,000 is realised, and we see no reason why it should not be, the increase since 1872 will have reached the enormous amount of nearly 190 per cent. London deliveries during the same period have increased in like manner, being 12,276,000 lb. in 1872, against 48,666,000 lb. in 1881, nearly 200 per cent.

During the last twelve months the imports of Indian tea (including Ceylon), into Melbourne, equals say—

1st July, 1881, to 30th June, 1882.....979,520
Against same time, 1880-81.....671,000

showing an increase of over 40 per cent. The whole of these imports have been sold, and no stocks are held in first hands, and only trifling quantities by the trade.

By public auction, some—
655,429 lb. weight, sold at 1s. 0½d. to 2s. 5½d. per lb. in bond.
59,175 „ „ 9¼d. to 1s. „ „
all Indian Tea, in addition to which some 51,435 lb. of Ceylon tea sold at up to 1s. 9d. per lb.—thus giving to Indian the position of having sold nearly one-third of all the better class teas sold by public auction in Melbourne, or say teas at over 1s. per lb. in bond.

Messrs. Cosmo Newbery & Dunn, who have analyzed nearly 800 samples of teas, have kindly furnished the following report, which is published in full and gives most invaluable and interesting information.

Industrial and Technological Museum.

Laboratory, 22nd June, 1882.

The following results shows the highest percentage of Extract we have so far obtained during our series of examinations to date:—

Locality.	Percentage of Mineral Ash.	Percentage of Extract.	Percentage of Soluble Salts.
Ceylon	4·16	53·18	2·58
India	4·82	52·85	3·04
China (Hankow)	5·82	52·80	3·26
„ (Foo-Chow)	6·30	46·71	3·27
Japan	5·78	49·90	3·28
Java	5·28	45·82	3·19

The samples of Indian and Ceylon teas were obtained from the Melbourne International Exhibition of 1880-81; the small percentage of Ash and Soluble Salts is probably owing to the rapid growth of the tea plant, and also the carefulness bestowed during the process of manufacture. The three last samples are the best that could be obtained, but we do not consider them as representatives of the "Finest Teas" that their respective localities are capable of producing.

The results of our examinations leads us to expect that each country is capable of producing a tea which contains the same percentage of extract.

J. Cosmo Newbery,
Frederick Dunn.

These teas may be classed as the highest standards (so far obtained) of excellence from the analysts point of view, which is also comfirmed from a tea taster's standpoint by the aroma and liquor of the teas analyzed. This result tends to show that all countries can grow the finest description of tea.

To the consumer, the question of the greatest importance is, how near do the teas of commerce go to the above standards. As far as Melbourne is concerned, the question is easily answered by the following tables, prepared from numerous analyses made by Messrs. Cosmo Newbery & Dunn—

Season 1881-82.	Percentage of Mineral Ash.	Percentage of Extract.	Percentage of Soluble Salts.
Average of 14,000 half-chests of Indian teas	5·56	43·71	3·15
Average of 13,299 half-chests of first crop Foo Chow Congous...	5·48	34·58	3·45
Average of 10,299 half-chests of second crop Foo Chow Congous	5·66	30·94	2·87
Average of six samples 300 half-chests of Moning Congous ...	5·71	36·94	2·92
Average of four samples 118 packages of Japan teas	5·16	36·32	3·27
Average of three samples 48 packages of Java teas...	5·51	40·64	3·27

The Moning, Japan, and Java teas, though sold in the market, are rather too small in quantity to give a fair average for this class of commercial teas.

It is claimed for India, and confirmed by the foregoing analyses, that her commercial teas rank far higher than those of any other producing country in the world, and are nearest to the highest standard of excellence as determined by one of the most exact sciences (chemistry), that civilized nations possess.

Professor Hassall writes—

"Tea owes its properties mainly to tannin, theine, and the volatile oil. The first gives it astringency, the second stimulates both the vascular and nervous systems, while the third acts not only as a stimulant but imparts the aroma, which is so characteristic of good tea, and which is grateful to many. The exerts it power chiefly on the nervous system. It excites the activity of the brain, and stimulates the flow of thought."

Professor Johnson writes—

"Tea exhilarates without sensibly intoxicating. It excites to increased activity and produces wakefulness. It soothes on the contrary and stills the vascular system, hence its use in inflammatory diseases and as a cure of headache."

Preparation of Rhea or China Grass.—At a recent meeting of the Paris Société d' Encouragement, M. Simon reported on the process of decortication devised by M.Favier, retired captain of Engineer corps. The greatest drawback to the use of the rhea, or China grass, is said to be the slight proportion of textile filament which it possesses. To reduce the time and expense of preparation, M. Favier places the stalks, freshly cut to lengths of five to ten feet, in a wooden receptacle, to which steam is then admitted. The outside covering is afterwards removed very easily by children.—*Journal of the Society of Arts.*

Curiosities of Grafting.—M. Carrière records in a recent number of the *Revue Horticole* a case wherein he grafted a Jerusalem Artichoke on to the stem of the Sunflower. The method of procedure is not stated, but a curious result followed, viz., the formation of tubers on the stem of the Sunflower, no tubers being found below-ground, although several were found on the stem just above-ground. We trust M. Carrière will give us further particulars as to this interesting experiment. The figure does not show how the graft was effected, nor whether the tubers were formed on the stock both above and below the graft. M. Carrière also figures a graft of the Tomato on the stems of Solanum Dulcamara. Our readers will remember the analogous experiments of Mr. Maule and Mr. Alexander Dean some years since.—*Gardeners' Chronicle.*

Charcoal Making in Kent.—This is done to a large extent in the Hop districts of this country, in order to supply the heavy local demand for drying Hops in the time of the Hop harvest. The old Hop-poles are largely utilised for the purpose. To prepare them for burning they are broken into lengths of 3 feet each, and placed for burning in stacks, which are formed of "cords" of wood, as they are termed. Some of the larger stacks are made up of three or four "cords" of wood, and the burners are paid so much per "cord." In forming a stack for building, a hollow place is left in the centre, and then the lengths of Hop-poles are sent up on end round this till the size required is obtained. It is usual to burn the upper parts of the poles only, leaving all the sound lower portions some 5 feet in length, in which form they are very useful for repairing hedges, &c. When these are too much decayed for this purpose they are burnt, but it is necessary to place the ends which have been dipped in creosote before being used with the Hops upwards, or they would not be consumed. They of course take a much longer time to burn through than do the undipped portions. The heap, when ready for lighting, presents a thick mass of upright pieces of wood, the heaps varying in size according to the quantity to be burned, and is from 14 to 20 feet in diameter. A layer of coarse straw is then placed over the heap of wood, and over this a covering of rough sand, 2 inches or so in depth, is placed. A quantity of red-hot charcoal is then dropped into the opening in the centre, which ignites the wood, and then the opening is covered over. The fire, therefore, proceeds from the centre to the circumference, and it occupies from a day and a half to three days to thoroughly char the mass. When sufficiently cooled it is cleared away into a shed ready for use, and another heap is formed, till all that is required to be burned is exhausted. The work is done by professional charcoal-burners, who take a kind of circuit, itinerating in various parts of the country. The best charcoal is made of roots of trees, but a longer time is required to convert them into charcoal—what is known as "cord wood"— that is, the branches of trees that are cut out to thin them, or blown down by the wind, and Hop-poles. The straw becomes thoroughly charred, and, being mixed with the calcined sand and small pieces of charcoal, makes an excellent manure for Onions, Turnips, &c. It is not unlikely that this charred sand and charcoal would prove an excellent ingredient for Auricula soil. There can be nothing injurious in it, being mainly composed of the finer particles of the charcoal; and the sand must be better after being burnt than before. Some of this sand will be used by an Auricula cultivator in his potting compost this summer, and it will be interesting to know how it answers. It would not be difficult to obtain some fine charcoal for potting purposes from some of the Kentish homesteads as the Hop-dressers do not care to use the fine among it, and prefer the coarse. The remains of a store-heap have to be sifted, and the siftings supply Auricula cultivators with what they appear to require to keep their soil porous and sweet.—*Gardeners' Chronicle.*

COFFEE CULTURE IN BRAZIL: FINANCIAL COST AND RESULTS OF TYPICAL PLANTATIONS.

The *Anglo-Brazilian Times* has published details regarding coffee cultivation in Brazil, which will be of special interest to our planting readers. From the figures given in the extract, it will at once be seen that money in Brazil, for estate purposes, is rated 2 per cent dearer than in Ceylon. The usual rate of interest for loans on coffee property in Ceylon has been 8 per cent, and as a very large proportion of our land has been opened with borrowed money the rate has seldom been calculated lower in estimating the cost of estates. In Brazil, it will be observed, the "interest on capital" (for no actual borrowing of money on mortgage is recognized in any of the cases furnished) is taken at 10 per cent, and the balance which remains from proceeds of coffee and "other produce," after the payment of all expenditure, including the "expenses of owner's family," is said to reduce the normal rate of interest (10 per cent) or to raise it. The latter process is shewn in only one of the cases given. In another case the balance left for interest on capital was below 2 per cent. The sums allotted for expenses of owner's family are so modest that we cannot help thinking they must be supplemented by plantation-grown meat and what in the West Indies are called "ground provisions." And this raises another question: although the sales of produce other than coffee are shewn in some cases, we do not find any reference to either cost or value of cassava, maize, rice, yams, or other food for the slaves grown on the plantations. Account is only taken of what is purchased: "jerked beef, clothing, &c." No doubt a certain amount of allowance ought to be made in the direction we have indicated. The vastly different conditions under which coffee culture is carried on in Brazil, however, when compared with Ceylon are shewn by the two facts that, while the word "salary" appears in these accounts, the allied term "wages" is nowhere inserted, and that the slaves who work the plantations are estimated at a value considerably beyond the aggregate of land, coffee bushes, buildings, machinery and terraces; the latter, no doubt, what we call "barbecues" in Ceylon, only that they are much more extensive on plantations in Brazil, where, so far as we know, there are no "curing establishments," such as we have at our port of shipment. All is done on the estates, unless there should be some exceptions of recent date at Santos. In view of the average rate of exchange, we may, for all practical purposes, take the Brazilian *mil* at 2s. This premised, our readers will observe that, while, in the case of the first estate, the value, with slaves, &c., is put down at £63,400, the land, equal to 4,700 acres, is rated at considerably less than one-third of this sum, viz., £19,400. The coffee bushes, estimated at 300,000, are valued at £6 000. The rate per tree is 200 reis = one-fifth of a mil, or somewhat under 5d. As in Brazil as well as Java, the coffee bushes are not pruned, but allowed to grow their full size, our usual calculation for both countries has been 300 trees per acre. Of the 4,700 acres of land in the first case less than one-third (200 times 6·7 acres), or say 1,340 acres, are planted with coffee, which gives less than 240 trees per acre. An extent of 134 acres is described as "virgin forest" for coffee," what we in Ceylon would call reserve jungle; four times that extent is in pasture, while two tracts, each equal to that in coffee, are described as "tired" (worn out?) land, and what we do not pretend to understand (can any person with local knowledge help us?) "cold" land. Is swampy land or land otherwise unsuitable for coffee culture indicated? We should also be glad to know why the "alquieres" differ so much in size—6·7 acres, 11·56, and so forth? It will be observed that the slaves are valued

Field hands at ... ... £120 each,
Artizans ,, ... £200 ,,

while 30 "servants" and 25 sick are lumped up at £5,000 for the whole, about £166 each. No doubt some of the so-called "servants" attend to cattle, pigs, &c.; but the unpaid-for service of a proportion ought surely to be charged against "expenses of owner's family"? It will be observed that for an estate of 4,700 acres gross, of which 1,340 are in coffee, the labour force is stated at 230. These are all valued as adults, but, of course, there must be children in addition, most of them born "free,"—after a fashion. Taking the field hands, 150, we get only 1 labourer for over 31 acres of the gross extent, or, for the 1,340 acres in coffee, a little under 9 acres for each. In our best times we used to have 2 coolies for 3 acres in Ceylon. Of course the slaves in Brazil are permanently employed, and neither are the trees pruned nor is the land weeded as with us. On the other hand the coffee in Brazil is prepared on the estate. Amongst the items of expenditure, by the way, is the curious entry "hire of sacks," so that the estates do not seem to have their own bags. Perhaps the muleteers or contractors provide them and charge for the hire? The items of transport to railway and its freight charge, with transport in Rio, we can understand, but will some expert help us to the meaning of "3 per cent commission on 4 mils"?—Oh, we see,—it is the broker's commission on coffee sold at 4 mils (eight shillings) per 10 kilograms (=22 English pounds). Besides the 10 per cent interest on capital, our readers will observe that the "amortization" of land (why 1s 3d in 36 years—is it a misprint?), coffee, buildings, terraces, machines and slaves is provided for under the head of "expense," as well as "10 per cent on 91,000 mils" (?) in addition to 10 per cent interest on capital. The item for amortization of 230 slaves, the period fixed being 10 years, is £1,597. Nothing is down for wearing out of implements, deaths of cattle, &c. But these are minor matters. Salaries of administrator &c. are shewn as aggregating £1,300, but probably the administrator and his subordinates, like the owner's family, get more or less estate produce. The valuation of this estate of 4,700 acres, it will be seen, is thus made up:—

Land...	£19,400
Coffee trees	6,000
Slaves	28,000
Buildings and terraces	7,000
Machinery, implements, cattle, &c.	3,000
Total...	£63,000

From that portion of the estate, 1,340 acres, covered with 300,000 bushes, the coffee gathered was 360,000 kilograms, or taking the kilogram at 2⅕ lb., a bearing rate of 583⅓ lb. per acre and 2⅔ lb. per tree. The proceeds of crop, all sold in Rio, were, at 4 mils per 10 kilos (8s for 22 lb.) 144,000 mils. or say £14,000. But as 849 reis, or not far from 1 mil, per 10 kilos were paid for transport, commission, &c., on each 10 kilos sold, the net proceeds were only £11,343-12, or £542-2 less than the "expense" taken at £11,885 10; "thereby" it is finally said, "reducing the interest on capital to 9·14 per cent."

Not a bad result, we should say, after fully providing for support of owner's family, amortization of slaves, &c. The great question, of course, is, was the establishment free of debt except to the capital of the owner? If so that owner might be called prosperous, provided a slave owner can ever know what true prosperity is. Our readers interested in the subject can make deductions from the rest of the figures, such as we have attempted to found on the first set. In the second case the interest on capital was down to 3·09 per cent; then comes 3·46: 1·88; 4·84; 3·72; 7·41; and in the last exceptional case 11·92, or nearly 12 per cent. With reference to the number of trees to the acre, we take the second estate with 1,400 acres of land, only 46 per cent of which is in cultivation, some of it with "other products than" coffee. Let us take 500 acres as bearing the 400,000 trees (old and new), and we get in this case the (for Brazil) high average of 800 trees per acre. Perhaps it may be owing to the number of old trees in this case that 400,000 gave only 88,132 kilograms, against 360,000 for 300,000 trees in the first case. In the third case we have 35 per cent (let us say one-third) of 1,392 acres=in round numbers 400 acres, bearing 300,000 coffee trees. The average in this case (like the last one, exaggerated, we suspect) is 750 trees to an acre. This São Paulo plantation yielded only 44,061 kilograms of coffee from 300,000 trees, or about 110 kilograms per acre, a poor result for the district of which Santos is the port. But probably a great many of the coffee trees were young. In the fourth case 200,000 trees are credited to about 300 acres, or at the rate of 666 trees to the acre. Even this is too high. The round numbers given for coffee trees look suspicious. The Minas Geraes estate gave the worst result of all, only 1·88 per cent on capital. A crop of 73,435 kilos in this case was somewhat over one-third of a kilo per tree, or 183½ kilos per acre. The equivalent in English pounds per acre is 401 lb. Of the fifth estate it said that 180 acres are in maize and beans and 24 in mandioca (cassava), while 70 per cent of the whole 1,900 acres is in pasture and "worn out" lands. Coffee trees numbered at 140,000 on 380 acres (468½ trees to the acre) gave 52,000 kilos of coffee (136 kilos or 299 lb. to the acre). The land in this case is valued at only £1,600, or £300 only in excess of the interest at 10 per cent of the whole establishment, the 55 slaves being valued at much more than the land. In the case of the sixth estate we have it expressly stated that out of a total of 250,000 trees only 150,000 are productive, the others being young. The trees would seem to be at the rate of about 625 per acre, but no reliable calculation can be made. It will be seen that yams and *rice* are grown in the 4 per cent of swampy land on this estate. In the case of No. VII, we are asked to believe, which we cannot, that 300 acres bear 250,000 trees; but 97,500 kilos of coffee from 300 acres is at the rate of 325 kilos or 715 lb. per acre. To shew how essentially different the conditions in Brazil are from those in Ceylon, we need only attract attention to the note attached to this case, "Unused land 57 per cent of whole area." On most estates in Ceylon every inch has been utilized. In the 8th and last case 30 per cent out of 195 acres of land are unused, and as "other products" were sold we suppose we may take 120 acres as bearing the 120,000 trees mentioned. As this would be at the rate of 1,000 trees per acre, there can be no doubt that the round number for trees is grossly exaggerated. the yield of 90,900 kilos from 120 acres would be equal to 757½ kilos or 1,673lb. (or 15 cwt.) per acre! The trees were probably scattered over a considerably larger area than 120 acres. Altogether the statements (correct enough, probably, as to number of slaves and some other details) can only be taken as approximations in regard to coffee bushes and yield per acre of clean coffee. Still the figures will be interesting to our readers as affording a glimpse of the conditions under which the Brazilians compete with us in the production of coffee. The chief differences are the large areas of land at the disposal of planters and the permanently bound labour force. But, if all were known about money borrowed, deaths and running away of slaves, with the shadow of impending emancipation, and no prospect of labour in substitution, it might be seen that the Brazilian planters are not normally better off than their brethren in Ceylon. Fungus, grub and bad seasons have sorely tried us, it is true; but there are insect and fungoid plagues in Brazil also, which may be at the worst as our troubles abate and prosperity returns to the land where coffee is and always has been grown by means of free labour. We have, at least, no emancipation measure to fear: and no utter failure of labour supply impending.

BRAZILIAN COFFEE.

(From the Anglo-Brazilian Times.)

In connection with the present or future of coffee in Brazil the question of the cost of its production has extreme importance. By the kindness of the German Consul-General of this city we are enabled to give extracts from returns, furnished by the proprietors, for the actual working of several important plantations in Rio de Janeiro, San Paulo, and Minas Geraes, situated not far from a railway:—

I.

Coffee plantation in the province of Rio de Janeiro, with 700 alqueires (of about 6·7 acres each) of land, of which 200 are planted, 200 "tired," 80 in pasture, 20 virgin forest for coffee, and 200 "cold" land.

Salary of Administrator, etc. ...	...	13,000
Expences of owner's family ...	...	5,000

Receipt: 360,000 kilograms of coffee at 4 mils. per 10 kilograms, 144,000 mils. deducting from which 849 reis per 10 kilos, for transport commission, etc., there remains net 113,436 mils., or 5,421 mils. less than the above expense, thereby reducing the interest on the capital to 9.14 per cent.

II.

Another return, in regard to a Rio de Janeiro plantation of 120 alqueires, or 1,400 acres of land, valued as 80,000 mils. having 150,000 new trees and 250,000 old ones, worked with 124 slaves, 8 of whom were domestics, gives

the value of the plantation, with its slaves, at 458,000 mils.

Expense: 64,836 mils viz:	Mils.
10 per cent. interest on capital ...	45,800
Amortizations	12,836
Jerked beef, clothing, etc	2,500
Salary, etc.	2,200
Family expense	1,500

Receipt: 88,132 kilograms of coffee at 4,330 reis per 10 kilograms, 38,156 mils; sale of other products 2,000 mils; total receipt 40,156 mils.; deducting from which transport and charges at 792 reis per 10 kilograms, there is net 33,187 mils.; or 30,648 mils. less than above expense, thereby reducing the interest on the capital to 3·09 per cent.

46 per cent of the area in cultivation.

III.

In one having regard to a San Paulo plantation, 40 to 50 years old, of 200 alqueires, of 11.56 acres each, of land or about 2,392 acres of land, valued at 21,500 mils., having 300,000 coffee trees and 74 slaves, 12 of these domestics, the value of the plantation and slaves, etc., is given at 225,500 mils.

Expense: 35,107 mils. viz:	Mils.
10 per cent interest on capital ...	22,550
Amortization	7,757
Jerked beef, clothing, etc.	1,000
Salary, etc.	800
Family expenses	3,000

Receipt: 24,078 mils. From 44,061 kilograms of coffee, at 4,330 reis per 10 kilograms, and 5,000 mils. from sale of other products; deducting from which transport and charges at 847 reis per 10 kilograms, there remain net 20,346 mils. or 14,760 mils. less than expense, thereby reducing the interest on capital to 3·46 per cent.

35 per cent of the area is in bearing with coffee.

IV.

In one, in relation to a Minas Geraes plantation of about 940 acres of land, worth 31,500 miles., having 200,000 trees and 43 slaves, 6 of them domestics, the value of the plantation and slaves, etc., is given at 196,000 mils.

Expense: 30,219 mils., viz:—

	Mils.
10 per cent. interest on capital... ...	19,600
Amortization	4,919
Jerked beef, clothing, etc.	2,000
Salary, etc.	800
Tax...	100
Family expenses	2,800

Receipt: 23,030 mils., viz: 22,030 mils. from 73,435 kilograms of coffee at 3 mils. per 10 kilograms, and 1,000 mils. from sale of other products; deducting from which transport and charges at the rate of 1,188 reis per 10 kilograms there remains 14, 06 mils. net, or 15,912 mils. less than above expense, thereby reducing the interest on capital to 1·88 per cent.

47 per cent. of the whole area is virgin forest, 15 per cent. pasture and "worn-out" land, 31 per cent. in cultivation.

V.

Another, in relation to a second Minas Geraes plantation of 160 alqueires, say 1,900 acres of land, worth 16,000 mils., having 140,000 coffee trees and 55 slaves, 16 of these domestics, gives the value of the plantations and slaves, etc., at 131,200 mils.

Expense: 24,645 mils., viz:	Mils.
10 per cent. interest on capital ...	13,120
Amortization	3,625
Jerked beef, clothing, etc.	2,000
Salary, etc.	4,900
Family expenses	2,000

Receipt: 24,016 mils., viz:

22,516 mils, from 52,050 kilograms of coffee. at 4,330 reis per 10 kilograms, and 1,500 mils. from sale of other products; deducting from which transport and charges at 1,180 reis per 10 kilograms. there remains 17,880 mils. net, or 6,765 mils. less than above expense, thereby reducing the interest on capital to 4·84 per cent.

70 per cent. of the area is in pasture and "worn-out" lands; 380 acres are in coffee, 180 acres in maize and beans, and 24 acres in mandioca.

VI.

Another, relative to a third Minas Geraes plantation of 75 alqueires, say about 900 acres of land, valued at 33,000 mils., having 250,000 coffee trees and 51 slaves, 5 of these domestics, gives the value of the plantation and slaves, etc., at 195,000 mils.

Expense: 31,660 mils., viz:	Mils.
10 per cent. interest on capital ...	19,500
Amortization	5,149
Jerked beef, etc.	2,051
Salary, etc.	1,960
Family expense	3,000

Receipt: 25,263 mils, from 63,158 kilograms of coffee at 4 mils per 10 kilograms; deducting from which transport and charges at 925 reis per 10 kilograms, there remains 19,421 mils., or 12,231 mils. less than above expense, thereby reducing the interest on capital to 3.72 per cent.

Unused land 32 per cent of whole area; 11 per cent in pasturage; 4 per cent swampy but producing yams and rice; and 53 per cent in cultivation, but only 150,000 coffee trees are productive, the remaining 100,000 being too young.

VII.

Another, relating to a fourth Minas Geraes plantation of 117 alqueires, say about 1,400 acres of land, valued at 60,000 mils. having 250,000 coffee trees and 57 slaves, 7 of these domestics, gives the value of the plantation and slaves etc. at 237,800 mils.

Expense: 37,916 mils. viz:	Mils.
10 per cent interest on capital ...	23,780
Amortization	5,181
Beef, clothing, etc.	3,500
Salary, etc.	3,500
Family expense	2,000

Receipt: 42,246 mils. from 97,500 kilograms of coffee at 4,333 reis per 10 kilograms, less transport and charges at 1,073 reis per 10 kilograms; leaving net 31,785 mils. or 6,176 mils. less than above expense, thereby reducing the interest on the capital to 7·41 yer cent.

Unused land 57 per cent of whole area.

VIII.

Another, in relation to a fifth Minas Geraes plantations of about 195 acres of land, valued at 19,800 mils. having 120,000 coffee trees and 38 slaves, 6 of these domestics, gives the value of the plantation and slaves, etc. 160,800.

Expense: 26,016 mils. viz:—

	Mils.
10 per cent interest on capital... ...	16,080
Amortization...	4,436
Beef, clothing, etc...	2,000
Salary...	1,500
Family expense	2,000

Receipt: 38,000 mils. viz:—

36,000 mils. from 90,000 kilos. of coffee, at 4 mils. per 10 kilograms, and 2,000 mils. from other products; deducting from which transport and charges on coffee at 988 mils per 10 kilograms, we get net 29,108 mils or 3,092 mils more than above expense, raising the interest upon capital to 11·92 per cent.

Unused land 30 per cent. of whole area.

COFFEE PRODUCTION IN BRAZIL: ITS VALUE AS COMPARED WITH THE WHOLE COMMERCE OF THE EMPIRE.

In the *Anglo-Brazilian Times*, attached to the figures relating to the value, expenditure on and proceeds of typical estates, we find the following striking figures:—

Export of Coffee from Rio and Santos.

	Rio Janeiro. Mils.	Santos Mils.	Total Mils.
1851-52 ...	31,055,324	1,523,992	32,579,316
1859-60 ...	51,319,118	7,623,652	58,942,770
1867-68 ...	70,785,039	9, 55,438	80,740,477
1875-76 ...	94,500,316	22,661,601	117,161,917
1876-77 ...	88,911,382	17,7.1 609	106,532,991
1877-78 ...	87,359,560	27,633,349	114,692,909
1878-79 ...	100,917,767	31,084,522	132,002,289

STERLING VALUE OF ABOVE TOTALS AND THEIR PERCENTAGE TO THE TOTAL EXPORTS OF THE EMPIRE,

	Exchange of d.	Sterling. £	To Total Exports, per cent.
1851-52 ..	27½	3,733,655	48·86
1859-60 ...	25⅝	6,293,368	53·21
1867-68 ..	23¼	7,821,735	43·45
1875-76 ..	27	13,180,716	61·31
1876-77 ...	24½	10,885,451	54·58
1877-78 ...	24	11,469,291	61·21
1878-76 ...	21	10,550,200	63·94
1879-80 ...	22⅝		

STERLING VALUE OF THE WHOLE EXPORTS OF RIO AND SANTOS AND THEIR PERCENTAGE OF THE TOTAL EXPORTS OF THE EMPIRE.

	Rio de Janeiro. £	Santos. £	Total. £	Per cent.
1851-52	4,180,716	262,711	4,442,427	58·16
1859-60	5,933,850	813,920	6,747,770	57·06
1867-68	7,877,930	901,930	8,779,860	48·78
1875-76	11,316,663	2,729.173	14,045,836	65·34
1876-77	10,315,300	2,147,740	12,463,040	62·75
1877-78	9,233,946	2,788,450	12,022,396	64·17
1878-79	9,280,270	2,765,179	12,045,449	66·67
1879-80	10,566,800	2,810,470	13,377,270	70·67

It will be observed that, while, in the seventeen years between 1851-52 and 1878-79, the value of coffee exported from Rio, the chief port of Brazil (we take the mil at 2s), rose from £3,105,000 to £10,091,000, or somewhat more than treble; in the case of Santos (the port of São Paulo, in which province slave labour has recently been concentrated), the increase has been from £152,399 to £3,108,000, an increase of no less than 2,000 per cent! The total increase in the exports from the two chief ports of Brazil in the seventeen years, calculated strictly in sterling, was from £3,733,655 to £10,550,200, or at the rate of nearly 300 per cent. (In consequence of high prices, the value in 1875-76 was no less than £13,180,716.) The proportion of coffee from the two ports to total exports, rose from nearly 49 per cent in 1851-52 to 64 per cent in 1878-79; so that coffee from other ports with sugar, cotton, and all other articles exported, only made up 36 per cent, or somewhat over one-third, against nearly two-thirds for coffee alone from Rio and Santos. Of course, other products, besides coffee, go from Rio and Santos, and when the value of these is counted the exports from the two great ports make up 70·67 per cent of the whole export trade of the Empire. The preponderance of coffee is overshadowing, but the concentration latterly of nearly all available capital and labour on this one product has been good neither for Brazil nor for the rest of the world—except, perhaps, to the consumers of coffee—or mixtures of which coffee forms (more or less) an ingredient. Coffee, in truth, has been overdone in Brazil, as tea is likely to be in India.

"MOCHA" COFFEE.

The following, from the official report on the trade of India just published, deals another blow at the farce of so-called "Mocha":—"Sending Indian Coffee to Arabia seems like sending coals to Newcastle, but the export is largely increasing:—

Years ended March 31st	Cwts.	R.
1876-77	4,954	1,48,632
1877.78	5,022	1,45,115
1878-79	5,737	1,86,382
1879 80	10,214	2,65,015
1880-81	12 561	13,54,289

Apart from such portion of this Coffee as may be required for local consumption, to supplement the deficiency caused by the export of the more valuable Arabian Coffee, and by the drought which for the last two years has more or less affected the Arabian Coffee-growing districts, it would seem to be the fact that, as stated in a previous review, this Coffee is made up for sale as Arabian Coffee—genuine Mocha."

The same Return has the following remarks on the general Indian Coffee production:—"There was a fairly large increase in the quantity exported, but a decrease in price and consequently of value. Rather over half of the whole exports were sent to England, and 133,736 cwt. to France. Of the rest, the greatest part was sent to Arabia, Persia, Turkey in Asia, and Egypt (36,217 cwt. in all), or about a tenth of the total exports. In addition to the quantity exported from British India, we should include 10,624 cwt. exported from the native states of Travancore and Cochin to arrive at the total exports of Indian Coffee in the year, They would thus amount to 379,981 cwt. Coffee Planters have been neglecting their business in a very unfortunate way for many months past, and have given their attention to speculations in land in connection with the craze for gold mining, which is sure to cause heavy losses with, what is worse, discredit of really sound Indian speculations by English capitalists. There were in 1880, 198.329 acres under Coffee cultivation in India, of which 106,036 were in Mysore and Coorg, and 73,587 acres in the Wynaad and other parts of the Madras presidency, the total outturn being stated at 33,100,778 lb.—*Produce Markets' Review.*

COFFEE PROSPECTS IN COORG, (S. INDIA).

MERCARA, 12th August.—There was some uneasiness felt by planters that the supply of Canarese labour for the coffee estates would this year be limited and in that case be the occassion of much loss: for with the construction of the Mysore State Railway, and the large pay offered to coolies by the many newly opened Gold Mining Companies, there was felt to be much fear of attraction. But it is not the case, for labour has never been more abundant than at the present time, and, as one quick-thoughted planter remarked, they just jostle one another. Add to this the country to the west of Mysore, from which our labour is drawn, has not for many years been favored with such a copious rainfall, whereby all the fields for cultivation, without exception are now and have been ploughed and sown with grain, which gives the villagers more work to do. Yet withal that, the supply is plentiful. An old Ceylon planter settled here has this year brought into Coorg about three hundred labourers from Salem or thereabouts; these men are giving satisfaction in their work. They offer a contrast in their feeding, they being omnivorous, to the upright Canarese coolies, who may be classed as graminivorous. The coffee crop will not be so large as that of the past year, there having been a very great failure of the spriog showers which instead of happening at the proper period of March when the ground was parched, and the trees only waiting for a timely shower to fall on them, to burst with renewed vigor and strength into blossom: the sky remained unclouded until May whereby the buds or spikes were scorched upon the trees; and when the rain did fall, and what blossom was remaining to come out, did shew forth the rains and high winds of a very early monsoon which quickly destroyed the greater part of that. In South Coorg the crop prospects are much more favorable, and another bumper season is hoped for, the berries are of good substance and well forward, there having been sufficient rain in March to bring out and set the blossom there. That striving pest, the borer, which for two or three years has been partly quiescent, is now causing havoc among the well-stocked and largely bearing trees: and upon several estates on difficult patches, from three to seven hundred trees in an acre have been dug out; and now that there is a break in the weather, they are

being burnt on the sides of the estate roads. But even this disaster is better borne than the leaf-disease, which subtle pest spreads and spreads and cannot be overcome but with vigorous measures applied quickly and in time to the borer, its increase is greatly checked. Moreover, I saw an estate last month in good condition, and bearing a virgin crop from its young trees, which had been replanted where the borer had destroyed the coffee six years ago. Of leaf-disease its attitude is highly pacific, and where a system of high cultivation is followed, as is the case in the majority of coffee estates, the evil effect is almost nil, and it is only upon the early ghat or forest clearing, where the pioneer coffee planters first embarked their enterprize, that the bad consequences are felt for here all nutrition has long since gone; the top substance being exposed to the sun and made friable, has been washed away in impetuous monsoons, causing the trees easily to succumb: so that from this experience, now all new coffee clearings are planted largely with coeval surface root feeding shade trees, which afford protection doublefold.—*Madras Standard.*

THE BLUE GUM LEAF DISEASE.

Of the disease in the leaves of *Eucalyptus globulus*, and of its effects not only on the trees themselves but on neighbouring vegetation, we have frequently written in these columns since the disease was first noticed about three years ago. It took the form of spots resembling smallpox on the leaves, and similar spots, more injurious than the originals in their results, spread to ledgerianas which it was hoped would have benefited by shelter instead of suffering from contagion by being planted close under the lee (the opposite side to that whence the south-west monsoon blows) of the Australian trees. Beyond loss of foliage the gums did not, at first, seem to suffer, and, although contiguous cinchonas and rose bushes were more injuriously affected, a few spots on the leaves of tea plants were reckoned of but little account. We referred specimens of affected leaves to Dr. Thwaites, C. M. G., who told us to look out for a "bug." But the presence of diurnal or nocturnal insect we have never been able to trace. Still stranger, Mr. S. Green, so well qualified as a naturalist and microscopist, has never been able to find on the affected leaves any specific fungus or the certain action of an insect. Leaves were sent to Mr. Marshall Ward by Mr. A. M. Ferguson, junr., and the Government mycologist merely replied that leaves of trees were frequently so spotted! He suggested neither cause nor remedy. Our own crude theory of the disease is, that it is a chemical change of an injurious nature in the juices and tissues of the leaves, owing to change of habitat in the tree from warm and dry to cold and wet. Until quite recently the affection was confined to trees on Abbotsford above the elevation of 5,000 feet. Now, we fear, it is spreading downwards, but for information on this head we wait. Before the writer left Abbotsford at the end of July, he felt anxious about the condition and effects of trees which it had cost him so much to establish as drainers of the soil and shelterers of other vegetation, and the introduction of which, he had, through the press, so earnestly (and honestly) urged on his brother planters. We left, hoping that as the disease had abated in previous years, without doing serious damage, so it would in the present season. But the heavy and long-continued wet of this monsoon brought matters to a crisis, and the conviction, which cost us many a pang, was forced on us by the reports which reached us, that, to save not only the cinchonas which we had left looking so healthy and luxuriant but even the much hardier tea bushes, we must consent to sacrifice the blue gums, at least to the coppicing of them. The trees were not only themselves dying but were spreading infection and denudation of leaf, canker of stems (in the case of cinchonas), and in some cases death all around them. From the tops downwards the cinchonas died off; a hedge of roses was left utterly leafless, and patches of tea bushes (for the first time seriously affected by the pest) were reduced to the same condition. "Wattles," never before shewing a trace of disease, were infected by neighbouring gums and killed, and the infection spread to rare Australian plants, around the bungalow, which had been sent to us by Dr. Bennett and Mr. Moore of Sydney. Our latest account of the disease is that it was down and doing damage at 4,900 feet above sea level, and our fear is that it may prevail even at lower elevations. Planters naturally, especially in these hard times, do not care to mention the appearance of pests, new or old, and we kept saying: "Surely this disease cannot be confined to Abbotsford. What about the gums on Oliphant at an average of nearly 7,000 feet; and what, especially, about those fine shelter rows of gums in the Lover's Leap cinchona plantation at the Kandapola end of Nuwara Eliya?" A visiting agent assured us recently that there was no sign of the disease on the Uva side of Nuwara Eliya, and, until our attention was called to a paragraph in the local "Times" indicating the presence of the disease in Dikoya, we had never heard of it beyond the limits of the property in which we were interested. We fear we shall now hear too much of it. If compelled to abandon the cultivation of blue gums, we trust we may be able to say that *Grevillea robusta* retains all its favourable characteristics. The great advantage of the blue gums was their exceedingly rapid growth and the prospect of good timber from them at ten years old. The *Grevillea* also grows quickly, and gives better shelter and timber than the *Eucalyptus*. We have already stated in the *Observer* that we saw square miles of *Eucalyptus* in Gippsland, bare of foliage and dead. But the cause of the destruction was a ravenous moth. Of fungus or chemical leaf disease we have never heard, as affecting the Australian trees, which, after all, attain their greatest perfection on such wet ranges as those above Fernshaw in Victoria, the scene of the growth of the highest trees in the world. These are *E. amygdylina*, to which *E. globulus* is only second in height. In the "*Tea Encyclopædia*" there are illustrations of diseased tea leaves, somewhat resembling in appearance those affected by the gum leaf disease, but below each drawing is the description "*pierced*" by the immature or mature insect. But in our case there are no marks of piercing. The "tea bug" or "mosquito blight" of India is undoubtedly *Helopeltis theivora*, a name changed by Mr. Moens in his later accounts of its deadly doings on cinchona and tea in Java to *Helopeltis Antonii*. If bad in India, this insect seems to be worse in Java. We said to our good host, Mr. Kerkhoven of Sinagar: "Why, may I ask, have you pruned your fine tea so unmercifully: down almost to the ground?" 'Sorely against my will," he replied, "but the remedy was rendered absolutely necessary by the ravages of *Helopeltis*." We took away a glass bottle in which specimens of these destructive insects, resembling large mosquitoes, were preserved in spirits, and which we handed to Mr. Green. But he has seen no sign of the insect, mature or immature, on the leaves we have submitted to him. In only one case did

he see anything like the piercing of a leaf. We trust, therefore, we have not the deadly "mosquito blight" amongst us, although we suppose that, on the principle of "where the carcase is, there will the eagles be gathered together," we must expect its advent some day. Except "red spider," the "tea bug" is the worst enemy of cultivated tea. In certain seasons the yield of particular estates, sometimes whole districts, has been reduced by one-fourth, one-third, and even one-half, by the ravages of these insect pests, known to Indian planters under the rather inappropriate generic term "blight." The rains of the monsoon have been so heavy that even the cockchafer beetles disappeared, and in India it is believed that heavy rains wash away the "bug" and the "spider." In any case neither insect nor external fungus was observed, although we suppose it would be unphilosophical to recognize fermentation in the leaf tissues except as the result of the presence of certain forms of fungi?

What renders our surprise and disappointment so extreme at the development of a malignant disease in the leaves of *E. globulus*, is the enthusastic estimate generally formed of the antiseptic powers of those very leaves, with their powerful volatile oil. Here is Baron von Mueller's summing-up in his elaborate description of *E. globulus* contained in his great work, "*Eucalyptographia*":—

"We have as yet no accurate pathologic data on the effect of the exhalation of Eucalyptus-forests on phthisic patients; but I anticipate, that in the same manner as the air of dense woods of Pines is apt to stay the inflammatory processes in diseases of the respiratory organs, so the vapors of our Eucalyptus-forests, the odor of which we so readily perceive and recognize, will likewise arrest the progress of these sad diseases, more particularly in their earlier stages, and probably more so than sea-air, notwithstanding its pureness, the atoms of bromine and iodine carried with it and the increased ozone, which it evolves. Indeed I should assume, that sanitarian dwellings could nowhere on the whole earth be provided for phthisic patients more auspiciously and more hopefully, than in mountains clothed with Eucalyptus-forests in extra-tropical Australia and at elevations (varying according to latitude from 1,000 to 3,000 feet), where the slightly rarified air of a very moderate humidity pervaded by Eucalyptus vapor together with the comparative equability of the temperature would ease the respiration greatly. This assumption is largely based on the facts, that no other gregarious trees in the world evolve essential oil so largely as our Eucalypts, unless perhaps some of the most terebinthine Pines of colder climes, and that thus is afforded most copiously an oily volatile emanation, befitted to absorb and condense oxygen into ozone, the most powerfully vitalizing, oxydizing and therefore also chemically and therapeutically disinfecting element in nature's whole range over the globe.

"Our Blue Gum-tree has on the whole exercised already on regions of the warm temperate zone a greater influence, scenic, industrial and hygienic, than any other single species of arboreous vegetation ever reared anywhere, even Pines or Oaks or other classes of leading trees not excepted. Thus it has transformed the features of wide formerly tree-less landscapes, has already afforded in many places timber and fuel for rapidly increasing settlements, and rendered also many a miasmatic locality permanently habitable. The sanitary influence of Eucalyptus-vegetation was surmised by more than one of the early Australian settlers, who however were reluctant to place their conjectures on public record without positive investigations and final proof. Mons. Ramel touched with a few words on this subject (Revue maritime et coloniale) in 1861, but Sir William Macarthur was perhaps the first to argue, very many years ago, that our freedom from ague here was mainly due to our extensive myrtaceous vegetation, in which the Eucalypts are prominent, although species of Melaleuca, Leptospermum, Pæckea and some allied genera are also gregarious in many parts of Australia. The incontestable sanitary effect of these prevailing Myrtaceæ throughout Australia, except in some of the tropical coast-tracts, must be ascribed to a complex of causes: 1st, the ready and copious absorption of humidity from the soil by Eucalypts and closely allied trees; 2ndly, their corresponding power of exhalation, much greater than that of many other kinds of trees; 3rdly, especially the evolution of peculiar highly antiseptic volatile oil; 4thly, the disinfecting action of the dropping foliage on decaying organic matter in the soil, Eucalyptus-leaves themselves not causing any noxious effluvia through their own decomposition. Thus during maceration, for artistic skeletonizing, Eucalyptus-leaves, unlike almost all other kinds of foliage, give off no disagreeable odor, as first observed here by Mrs. Dr. Lewellin. The disinfecting and deodorizing virtue of the tree being unquestionable, it has even been placed in the wards of continental hospitals, a measure initiated by Drs. Mosler and Goeze of Greifswald and here insisted on by Dr. Alexander Buettner. The fresh bruised leaves can with advantage be employed for the dressing of wounds to prevent or subdue septic inflammation, especially when no other remedies are at hand. Possibly the Blue Gum-tree is even a better scavenger of back-yards than a weeping willow, and in so far safer as it does not intrude into the foundations of buildings and leaves no putrefying foliage. Indeed the sewage-question of cities in the warm temperate zone would become very much simplified, if each house had at its rear the evergreen Eucalyptus tree. Mr. Th. Taylor found that albuminous compounds could be preserved in water, which by mere maceration of leaves of E. globulus had absorbed some of their oil and perhaps other preservative particles, a few drops of oil added to water serving the same purpose. Other kinds of volatile oils act very variously in this respect. To Bacteria and other micro-organisms Eucalyptus-oil proves as fatal as Phenic Acid; hence also, as Taylor observed, it may be injected into the veins and arteries of cadavers for purposes of preservation. Flesh of any kind is as well preserved by Eucalyptus-oil as by Creosote, while beef sprinkled with it will dry hard without putrefaction. This writer is inclined to attribute the hygienic action of the oils of Eucalyptus and Pines simply to their high oxydizing power exemplified in the decomposition of miasmata. He recommends Eucalyptus-oil to be applied as an admixture to dressings in Gangrene. (*See* Report of the Department of Agriculture, Washington, 1876, pp. 82—86.)" The Baron makes no reference to the possibility of the leaves becoming diseased and being the source of disease in other vegetation. A. M. F.

OUR COFFEE CROPS:—SECONDARY AGENCIES AND THE FIRST CAUSE.

We call attention to the letter of "P. T. L." on page 311, and we must, in justice to ourselves, add a note to what this able writer says, to indicate our sympathy with the man who, in a somewhat similar crisis, says what the late General Skobeloff said when his attacking force was almost annihilated, "I blame no man; it is the will of God." On that position, we, who are not agnostics, must fall back, when, having done our best to understand and regulate secondary causes, we are compelled in a species of despair to give the problem up and fall back on

the wise though mysterious will of a First Cause. Accumulated adversities may be as much for our good as they undoubtedly were in the case of Job (N.B.—That Satan was *permitted* to be the instrument of the trial), and prosperity may, as in that case, return when, in deepest humility, we cease to question and rebel. So much for the supernatural element in the argument. As to the natural, we most keenly appreciate the evil effects of want of shelter, and on the property in which we are interested we took pains to leave belts. But in the most complete shelter of such belts coffee bushes and cinchona trees have died off after a very trying fashion; while now the very trees we planted for shelter are turning out sources of mischief! The scriptures recognize the possibility which we dare not contest that God may have a controversy with a people or a land and may visit for disciplinary purposes with mildew, blight and "abnormal" seasons. Those who believe this are not all ignorant fanatics, but persons who reconcile their creed with the most intense study of the nature and tendency of secondary causes.

THE VALUE OF CINCHONA TREES.

We call attention to the letter of our correspondent "S. T. R." on page 311, in order to say that our latest revised estimate of the value of Cinchona will be found in the introduction to our "Handbook and Directory for 1882," page 31, where, after giving information as to returns, we add :—

It is exceedingly difficult to fix on even an approximate value for Cinchona plantations, but as of some interest, even if inapplicable in most cases practically, we give the following :—

*Approximate Value of Cinchona Trees in the Hill Districts of Ceylon.**

Age. Years.	*C. Succirubra.*† (Red Bark.) Per Tree.	*C. Officinalis.* (Crown Bark.) Per Tree.	*C. Calisaya Ledgeriana.* (Yellow Bark.) Per Tree.
	Description:		
	R.	R.	R.
2 ...	1 ...	1 ...	1½
4 ...	3 ...	3 ...	4
6 ...	6 ...	7 ...	8
8 ...	10 ...	12 ...	15
10 ...	15 ...	18 ...	22

Officinalis will stand closer planting than succirubra, and the price obtained per lb. for the bark is very much greater, but the yield of bark is much less, so equalizing the value of the trees up to a certain age We merely offer these figures as a basis of calculation. The need of caution in estimating the value must be recognised when it is remembered how cinchona plants die out prematurely—to such an extent that a maximum loss of 90 per cent has been reported. Even after three years, a liberal allowance for probable losses must be made. At four years of age the tree, if cut down, has a good marketable value, provided an average growth has been made, and perhaps therefore our figure may be deemed too low by proprietors of flourishing trees of this age. It is impossible to give a scale applicable to all circumstances. Our column for Ledgeriana is entirely conjectural: few or no results being available to show the value of trees of this kind grown in Ceylon.

* A cinchona planter, who has seen these figures, writes that he would halve our returns, "for, while a single tree by itself may prove of this value, what with dying out and here and there dwarfed specimens and large patches where cinchona *will not* come on, any area of 500 acres would prove the truth of this suggestion"; but our friend overlooks the fact that our valuation is per tree, not per acre.

† We are reminded that the Officinalis-Succirubra hybrid (*Pubescens*) would be about 50 per cent more valuable than Succirubra.

MAJOR FERGUSSON IN INDIA: COOLY LABOUR FOR NORTHERN AUSTRALIA.

"Cooly labour for the Northern Territory" is the title of an instructive paper recently presented to the Parliament of South Australia. It contains Major Fergusson's report on his mission to negotiate with the Government of India for coolie emigration, and narrates many facts bearing upon the subject, incidentally mentioning also the steps taken by the Government of our own colony in dealing with this question.

Major Fergusson describes his visit to the Demerara Emigration Depôt near Calcutta, in company with Dr. Grant, the Protector of Emigrants for the Government of India. He saw a party of 500 coolies just returned from Demerara, and close by another large party about to embark for the same place. The returned emigrants he describes as looking healthy, happy, and prosperous, their children fat and very unlike native children in India. In reply to his questions they agreed that British Guiana was very a good place, and that they had been well treated aboard ship. They had brought back an average of two hundred rupees a head. Those about to embark looked as a rule miserable half-starved wretches, chiefly from the Oude and the north-west provinces, from Benares, Patna, and Allahabad, and a few from Delhi. The conditions of their engagement were read over to them, and they were afterwards called up singly and asked whether they understood the conditions, and went voluntarily. Two made rather doubtful answers, and were kept back for further examination. Major Fergusson afterwards, in company with Mr. Firth, the Emigration Agent for Demerara and Natal, paid a visit to the ship from which the return coolies had landed. The doctor of the ship informed him that the death-rate did not exceed three or four per voyage, and that the coolies were quiet and orderly. The huts provided for the coolies whilst awaiting embarkation are long thatched buildings, the sides of which were formed of a sort of native mat, held upright by light bamboos or of mud, after the fashion of the "wattle-and-dab" of Australia. The whole cost of the depôt, capable of holding 1,200 coolies, was about £200. This is situated on the banks of the Hooghly, not more than two miles from the terminus of the main line of railway from Bombay and the Punjaub. Sir Ashley Eden, Lieutenant-Governor of Bengal, with whom Major Fergusson had an interview, is most favourable to coolie emigration, and he recommends their shipment at Madras, as the mortality would be much less than among the Bengal coolies, perhaps because they live better; besides which there would be less trouble in rationing them, as they eat meat and have fewer caste prejudices. This advice correspondents with that given by Mr. Hepburn, a coffee planter in Mysore, who was a fellow passenger with Major Fergusson in the rome.

During his stay in India Major Fergusson was summoned to the Council Chamber, where the Governor-General in-Council was engaged in the discussion of the South Australian Bill. The nature of the questions put to him on that occasion give additional proof of the almost paternal care of the Government for the coolies. They were anxious that the Protector of Immigrants in the Northern Territory should be a man in every way qualified for the post, and even contemplated offering to pay him It was pointed out that the Government of South Australia would probably agree to this, and would even be willing that

the officer should be appointed by the Indian Government, but that in any case he would have to be under the authority of the South Australian Government. It appears that among the employments to which it was proposed to put the coolies on arrival in the Northern Territory was that of railway making, and eventually in the mines and on the goldfields; but during his audience with the Governor-in-Council, Major Fergusson saw so clearly the opinion of the Indian Government that he pressed only for their use in railway construction, and is hopeful of securing this as a concession to which his Government attach great importance. He says the Queensland Government have not secured the right to employ coolies in other than agricultural pursuits, and mentions that there have lately been great objections raised to the employment of coolies on the tea plantations of Assam, and the Government are disposed to watch jealously over the disposal of the coolies after emigration. Major Fergusson feels that to press for leave to employ them on goldfields would very likely result in a refusal to allow them to work on railways, and points out that, in engaging the coolies, it will be necessary in each case to specify what they are to be employed in.—*Queenslander.*

SCIENTIFIC ROAD-MAKING.

The *Federal Australian*, in its Scientific Supplement, publishes the following letter on the subject of road-making, a question which is exercising the London metropolitan boards, the American cities, and nearly all the Australian capitals. Mr. P. Behrendt, C. E., says :—

"A city with architectural ornaments and monuments, but having miserable roads, is like 'a woman wearing jewels and ragged clothes at the same time.' This saying of a German philosopher is very suitable for Melbourne, and as the councillors of this city have now taken to their hearts the miserable state of the roads, and are talking earnestly about the best manner of building good roadways, I hope you will kindly allow me space on this occasion for the following remarks on roadways in cities :—

"Four conditions ought to be fulfilled by any good roadway :—1. A road must cause a minimum of resistance against a load moved on wheels. 2. The durability of a road must be a maximum. 3. The cost of making and of the maintenance of a road must be a minimum. 4. The road must not injure the health of the inhabitants of the city. That a road must have sufficient strength to bear the heaviest traffic is a *conditio sine quâ non.*

"I take into consideration stone pavement, wooden pavement, and asphalt pavement, bringing these three systems into comparison with our well-known macadamized roads. The following figures, compiled by me for this purpose, will give a clearer idea than a long disquisition; they are the results of observations in America, England, France, and Germany :—

System.	Resistance.	Duration in Years.	Cost of making per square yard.	Cost of Maintenance per square yard.
			s.	d.
Macadamized roads	·023	8	40	16
Stone roads (porphyry)	·020	13	28	9
Wooden pavement	·018	11	16	17
Asphalt pavement	·013	20	26	13

"According to this table, asphalt pavement is the best, and in my opinion there is no doubt that this system will be the pavement of the future for all large cities. Wooden pavement is most used in America, but even there the engineers relinquish it, and New York is going to build asphalt roads. Should the councillors decide for wooden pavements, they ought to use 'asphalt-wood-pavement,' which would be not only the best, but also the cheapest; and if any system has a future, it is this one. It has been tried quite lately in London, and the price was 12s 6d per square yard.

The faults of wooden roads are generally the following ones :—1. The construction is in most cases very costly and takes much time. 2. The maintenance is always very costly. 3. Wooden pavement is very dangerous in cases of fire—example, Chicago. 4. It does not last long enough, at least not in comparison to the expenses of building. 5. Some wooden pavements cause injurious evaporations.—*Queenslander.*

THE AUSTRALIAN TEA SEASON OF 1881-82.

Mr. Robinson, the commercial editor of the Melbourne *Age*, who once visited Ceylon and is a warm friend of our tea, gives a clear and able review of the tea trade of Australia in general and Victoria in particular, shewing that in the season ended 30th June 1882 the imports of China teas had been even more overdone than in the previous season, while the same tendency seemed still to prevail, notwithstanding accumulated stocks, and although in last season no really fine teas had been received from China. The sales by auction at Melbourne proved this :—

3,926,760 lb. sold at 4d to 1s per lb. in bond.
1,528,280 lb. sold at 1s 0¼d to 1s 10d per lb in bond.

This shows a slight decrease as compared with 1880-81 in quantity of teas sold over 1s per lb., and the entire increase of 1,000,000 is on teas sold below 1s per lb.

The exports of tea from China to Australia had risen in three seasons from 15 millions of pounds to 22,700,000. The proportion sent to Melbourne had risen in the same period from 8 millions of pounds to 12,490,000, but this included in the past two seasons tea from India and Ceylon to the extent of 671,000, and 980,000 lb. in each season, respectively. About one-third of the tea imported into Melbourne was exported to the other colonies. As the population of Victoria is increasing very slowly, the increase in the consumption of tea, from 5,611,000 lb. in 1878-79 to 7,381,000 in 1881-82, is the more gratifying. The heavy stocks of teas in bond in Melbourne were of low class China, 8d per lb. and under. Stocks of Indian were trifling in amount, and more of this kind was wanted. We find the editor stating of China teas :—

No choice S. O. pekoes came to hand, and we notice a decided falling off in the use of this tea, which is perhaps just as well, for it is only an artificially scented tea, a make belief used to give ordinary congous that lack the true tea scent a substitute for same.

Whilst on this subject we should be glad to see all high burnt teas ostracised, and give place to the well fermented and carefully fired article, with a rich, fine and true flavour of tea

Our crusade against artificially colored tea &c., and other rubbish akin, which the gentle almond-eyed foreigners offered to us as substitutes for genuine tea, has been to some extent successful, and we are glad to report a heavy falling off in the imports from Canton, which we hope will still further be checked by the operation of the Tea Act now in force.

It is satisfactory to find that the shipments to hand of new teas, 1882-83, are turning out much better in quality, especially Paklum. No doubt the restrictions of the Tea Act have something to do with this.

The notice of Indian and Ceylon teas we quote in full :—

Indian teas as anticipated by us, show a large increase in sale and consumption over the previous season. The following are the imports from India, including Ceylon, into Melbourne for :—

	lb.
1880-1881	671,000
1881-1882	979,520

The total sales by auction are for seasons.

	lb.
1880-1881	561,000
1881-1882	766,039

Privately, about 200,000 lb. weight has been placed. No stocks remain in the hands of importers, and very little in the hands of the trade. By public auction some 684,679 lb. weight sold at 1s 0½d to 2s 5½d per lb. in bond, and 81,360 lb. sold below that.

Some eight public auctions have been held in Melbourne of the Calcutta Tea Syndicate's teas, and on the whole each sale has shown a slight advance over its predecessors and responding to the like advance in prices taking place in Calcutta.

In spite of the heavy advance established on the lower grades, the teas continued in strong demand all through the season, and probably double the quantity could have been placed on the market without seriously affecting prices. The Darjeelings turned out exceedingly well, and, as last season, continue favorites with buyers ; prices ranging up to 2s 5½d per lb. in bond.

Assam and Cachars came forward in larger quantities than last year, and some very choice pekoes merited a better price than obtained viz., 2s 4d per lb. in bond. Taken on the whole, these teas were well liked, and the bulk of them are used for bringing up China teas. Darjeeling Terai, Chittagong, Doars, Kangra's, &c., in smaller quantities, all had attention and brisk sales. Debra Doons are liked for their appearance, but the liquor does not come up to expectations. Broken teas and broken pekoes, which at first were neglected by the trade, are now in strong demand at high prices owing to their value being appreciated for blending purposes. The following statistics show the increase in the growth of tea in India :—

The crops of Indian tea during the past ten years have been as follow :—

	lb.		lb.
1872 ...	17,900,000	1877 ...	35,800,000
1873 ...	19,750,000	1878 ...	35,000,000
1874 ...	23,300,000	1879 ...	40,000,000
1875 ..	26,100,000	1880 ...	46,500,000
1876 ...	29,400,000	1881 ...	48,300,000

Ceylon teas show only a trifling increase over last season, say :—

	lb.
1881-1882	63,630
1880-1881	54,000

These quantities are included in the sales of Indian teas.

The teas gave satisfaction, and are in strong demand, but much larger quantities should be sent if the Sinhalese hope for a permanent market in Melbourne. We notice the *Ceylon Observer* advises large areas of land being now devoted to tea cultivation, so we may hope to see this British colony soon figure more largely in her export returns of tea. Let us hope that there is a brighter future in store for Ceylon, and that the growth of tea will prove more profitable than the growth of coffee has lately done, and that the resistless energy of our race will again bring Ceylon into the foremost position of British colonies.

The Japan teas were said to be deteriorated by too high firing, while of Java it is said :—

Java teas to a trifling extent have again appeared on the market, and some of the teas show improvement in liquor. About 23,000 lb. weight sold at auction at 8¼d to 1s 5½d.

THE NORTHERN TERRITORY

of South Australia has been largely discussed and in very opposite senses as to its capabilities. Professor Tate, of the Science Department of Adelaide University, who ought to be an authority, has reported pretty favourably of its metalliferous resources ; less favourably of its pastoral cabilities, while we give just as it stands his qualified opinion of its fitness for the culture of tropical products :—

AGRICULTURAL RESOURCES.

So very little has been done to test the agricultural capabilities of the country that the question, "Are the climate and soil of the Northern Territory suitable for the growth of tropical plants of economic value ?" is still open for discussion. The soils of the valleys and of the hill slopes are, in my opinion, ill-suited for agriculture ; and with a few exceptions the land seen under cultivation was only that reclaimed from the jungle. The chief of the exceptions to which I allude is the soil formed by the decomposition of the diorite rock, massed between Port Darwin Camp and Yam Creek Telegraph Station ; it shows great capabilities, if I may judge from the healthy growth of the great variety of culinary and fodder plants under cultivation by the Chinese. Corroborative evidence of its richness is afforded by the reappearance of the graceful palm, Kentia acuminata, and, if it really be that species, in a more luxuriant state than it assumes in its northern stations. It abounds about Fannie Bay, near Palmerston, and occurs at intervals as far south as the Stapleton ; thence its place is taken by the fan palm, Livistona humilis, which is less choice in its habitat. My opinion of the unfitness of the country generally for agriculture is based on observations. 1. On the nature of the soil ; 2. On the general character of the indigenous vegetation ; and 3. On certain meteorological phenomena. The "desert sandstone" tableland I leave out of consideration as it is conceded by all who have traversed it that, with the exception of isolated tracts of the basaltic formation, agricultural operation is impracticable. The prevailing uniformity of rock structure makes it easy to generalize upon the capabilities of the soil. Thus, we have a dry, gravelly, iron and quartz *detritus* on the slopes of the metamorphic sandstone ; stiff clays with humid surfaces on the metamorphic slates ; barren sands upon the granitic surfaces—all of these are comparatively worthless for agriculture. Whilst the soil upon the coast cliffs is generally condemned, Captain King, in his narrative of a survey of the coasts of Australia (1818-22), writing concerning Raffles Bay, says, "The soil in some parts might be called even rich ; there were, however, very few places that could bear so favourable a character," vol. I., p. 85. And again, "The land about Port Patterson appeared to be barren and arid," vol. I., p. 271. Captain Stokes, in his discoveries in Australia, expresses the same opinion regarding the Port Essington District. At p. 386, vol. I., he writes : "Generally speaking, however, there is a great deficiency of land fit for cultivation" ; and again, "The capabilities of the soil, though it has by some been pronounced totally unfit for agricultural purposes, are still supposed by others to be great, and it is believed that rice, cotton indigo &c. might be raised," loc cit., p. 389 Alluding to the same area. Jukes, in the voyage of the Fly vol. 1 . p 351, says "The soil generally seemed of the poorest and most sterile description." There are patches of good, if not rich soil most undoubtedly ; but in the aggregate they form a very small fraction of the region of the northern rivers. The opinions touching the capabilities of the soil about the tidal portions of the rivers are very conflicting. King describes the soil abutting

on the Alligator and Liverpool Rivers as a sour stiff clay—Op. cit. I., pp. 104 *et* 259. Stokes says, "While the banks [of the upper part of the tidal portion of the Adelaide] were low—a circumstance very favourable for irrigation and the cultivation of rice."—Op. cit. I., p. 415. Jukes writes, "That rice might probably be raised in small quantities on the borders of the lagoons."—Op. cit., p. 361. I have reproduced these observations because they have reference to portions of the Northern Territory with which I am unacquainted. The meteorological phenomena, which must have a depreciating influence on the value of certain soils for particular crops, are—(1) The intermittent character of the rainfall at the chief period of growth. Many successive days of unclouded sky and hot winds during the wet season must have a deterrent effect on the growth of succulent plants and shallow rooting annuals in particular. (2) The rapid diminution in the amount of rainfall, proceeding in a southerly direction thus starting with a yearly average of 76·89 inches at Southport, it gradually decreases at the rate of abont one inch to every five miles, to 39·23 at Pine Creek. (This will be seen on a reference to Mr. Todd's reports.) The productions of the soil of the Government Gardens at Fannie Bay, reclaimed from a dense jungle, afford evidence that a great variety of useful plants may be successfully grown under similar conditions of soil and situation. But, as I have just shown, the climatic conditions change so rapidly as we recede from the coast that I am dubious, even other things being the same, whether equal results will be gained in the more inland tracts. If we turn our attention to the dominant vegetation we find that it implies, if not sterility of soil, then certainly the absence of those points of character indicative of permanency of atmospheric moisture, and conversely general exposure to the sun. Thus we note the absence of dense lofty forests, scarcity of ferns and epiphytic orchids, no lichens, no liverworts, and only four species of mosses having a very limited range of distribution. However, I believe that in several parts of the colony various species of Gossypium [cotton-plant), rice, and indigo could be cultivated, and a fair or even prolific crop obtained. Indeed, good cotton has been produced within the Murray basin (see F. von Mueller, "Select Plants for Cultivation," p. 99, 1876). The rice-plant is indigenous to the Northern Territory, having been found by Baron F. von Mueller in the marshes about Hooker's Creek, by Mr. Wilson in the marshes of the valley of the Norton-Shaw River, and by Mr. J. A. Giles in the valley of the Birdum Creek. The tamarind is also a native, having been noticed first by Leichardt at Port Essington, and subsequently by Mueller on the cliffs at the entrance to the Victoria River. Another useful plant indigenous to the country has been overlooked. It is Tacca pinnatifida, from the tubers of which the main supply of the Fiji arrowroot is prepared. I noticed it growing in rather humid gravelly soil here and there from Palmerston to Pine Creek.

We think it quite probable that a good deal of land with a suitable climate is avilable near the coast, if only the labour difficulty can be overcome.

THE RAINFALL OF THE GLOBE.

Nature reviews, in an interesting and, no doubt, scientifically correct fashion, a paper recently published on this subject by Professor Loomis of America. There is so much of value to Ceylon readers, and especially to those who take an interest in the causes of deficient rainfall that we make the following extracts :—

Leaving out of consideration all exceptionally heavy rainfalls, confined to limited spots, such as those of Cheerapunji, in Assam, which amounts to 492 inches annually, and the Stye, in Cumberland, which is about 190 inches, the heaviest rainfall is met with in the rain-belt, which surrounds nearly the whole globe, lying between the north-east and south-east trade winds. Absolutely the largest rainfalls over large regions are to be found where the trade-winds after having traversed a great breadth of ocean, are forced against and over a breadth of land of some elevation and extent which lie across their path. Of these the best examples are the highlands of Java, Sumatra, and Assam, in the Old World, and parts of the north of South America, and of the steep slopes of Mexico facing the Gulf of Mexico in the New World, over which the trades or monsoons discharge their moisture so copiously as to raise the rainfall over large tracts up to and in cases considerably above 200 inches annually. The influence of height is well illustrated by the rainfall of Mauritius; thus, while at the observatory it is 46 inches, it amounts at Cluny to 149 inches on a mean of the same 19 years. Similarly in St. Helena, while near the sea level it is only 5 inches, at a height of 1,764 feet it is 48 inches. In Ascension no part of which rises to any considerable height, the annual rainfall is only 3 inches, and the whole island is little else than a burned-up desert. The rainfall is particularly large in mountainous regions in both hemispheres above lat 40°, situated on the eastern shores of the great oceans, and consequently in the full sweep of the strong westerly winds of these high latitudes. Thus large portions of Scotland north of the Clyde, one or two small patches in England, a few spots in Ireland, large tracts between California and Alaska, the south of Chili, and the west coast of the south island of New Zealand have an annual rainfall exceeding 80 inches. Nay even at Bergen, lat 60° 23′ N., bathed in the warm, moist westerly winds of the Atlantic, the rainfall is 73 inches annually, which is the largest rainfall yet observed any where at so high a latitude. Those headlands, even though of comparatively small height, which run out into the sea, meeting the moist oceanic winds, have rainfalls very considerably above the average—owing doubtless largely to the greater friction of land than water on the winds, thus partially arresting their progress, and inducing a more copious precipitation. As causes of deficient rainfall, Professor Loomis enumerates five, viz :—(1) a uniform direction of the winds during the year, such as prevails within the regions of the trades, illustrated by the rainfall of Ascension, Sahara and South California; (2) the prevailing wind having crossed a mountain range, thence descends on the leeside, illustrated by the desert of Gobi, Chili and large tracts in Spain; (3) ranges of mountains so high as to obstruct the free movement of the surface-winds towards the interior, as parts of Central Asia and California; (4) remoteness from the ocean measured in the direction from which the wind proceeds, illustrated by the gradual diminution of the rainfall on advancing eastward into Europe; and (5) high latitudes, since beyond lat. 60°, at a little distance from the ocean, it seldom exceeds 10 inches, and there are apparently large tracts in North America and Asia where the rainfall is less than 10 inches. As regards this last statement, observation scarcely bears it out, since in the Europe-Asiatic continent, only two stations in latitude above 60°, viz., Kola in Russian Finland on the Arctic Sea and Yakutsk show rainfalls less than 10 inches, and these are doubtful owing to the short periods over which the observations extend. The truth is there are other causes powerfully influencing the distribution of the rainfall, than these which an examination of the rainfall of the individual months, notably January and July, best discloses. These causes have their explanation in the sys-

tems of low and high pressures, which appear and disappear with season. Of these the most prominent are the low pressures which occupy the centres of continents in the summer months and the northern portions of the Atlantic and Pacific Oceans in the winter months; and on the other hand, the high pressures which fill the centres of the continents in the winter months and the high pressures in the oceans immediately to the west sides of the great continents, about lat. 36°, as shown by the Admiralty's physical charts of the Atlantic, Pacific, and Indian Oceans. To take, as an example, the great summer barometric depression of Central Asia, with the winds flowing in upon it on all sides vertically carrying with them the moisture of the ocean from which they come. Thus East Siberia is then swept by south-east and East winds, which distribute to westward as far as Irkutsk, in July, a monthly rainfall of 3 inches and upwards. Now since the annual rainfall of this region is all but wholly determined by the rains of the summer months, the extension of these rains inland wholly determines the position of the annual iso-hyetal lines. Again, to westward of long. 100° in Siberia, the rains have their origin in the Atlantic and Arctic seas, and since west and north-west winds prevail from Archangel to Central Asia, they bring with them comparatively so large a share of moisture from the ocean, as to raise the annual rainfall over the greater part of these northern regions to about 20 inches, or even more. On the other hand, on the east side of the Ural Mountains, which drain these winds of much of their moisture, the summer rainfall is much less. From north of the Caspian and Aral Seas, southward to the Persian Gulf, and eastward to the Indus, the summer winds are north-west and since they thus advance over regions rapidly rising in temperature, little if any moisture is deposited in their train, thus rendering this extensive region one of the largest arid tracts of the globe. These, with other considerations, indicate that the courses of several of the iso-hyetal lines, where observations are sparse, should be regulated to a greater extent than has been done in the map before us, by the positions of river-basins and mountain ranges in their relations to those seasonal winds, which really determine the annual amounts of the rainfall. One of the most important points to which attention is drawn by Professor Loomis, is that more rain falls on the eastern than on the western sides of continents. This remark holds good everywhere, until we reach the higher latitudes of both hemispheres, where the predominating winds become westerly. Thus the rainfall at San Francisco is only from a half to a third of the amount which falls on the coast of Pennsylvania in the same latitude; and about the same proportions, or even proportions still more striking, are seen on comparing Morocco with the Chinese coast, and the west with the east coasts of South Africa, Australia, and South America. The explanation is to be found in the portions of the areas of low and high pressures, with their accompanying winds, during the season whose rainfall determines the annual amounts. On the east side of the continents the prevailing summer winds are south-west, south or south-east which, having traversed a large extent of ocean, and constantly advancing into higher and colder latitudes, spread a copious rainfall over the regions they traverse. But on the other hand, since the west side of continents in the same latitude lies between the region of abnormally high pressure in the ocean immediately to westward, and the low pressure of the interior, north-west winds in the northern, and south-west winds in the southern hemisphere prevail there; and as they advance into lower latitudes or ever regions of a conssantly increasing temperature, the deposit little or no rain in their course. Hence, owing to the failure, more or less complete of the summer rains it follows that the annual rainfall of these portions of the continents is small.

COFFEE ADULTERATION IN ENGLAND.

Owing to the immense pressure of other business, and also no doubt to the strong influence brought to bear by interested parties, the Government propose to abandon the instalment of fair play announced to be given to the Coffee trade at the time of the Budget, and to substitute a scheme, the effect of which would be to legalize every form of adulteration. Mr. Gladstone stated that the Treasury were only concerned with revenue matters, and not with adulteration. The latter offence could no doubt be dealt with under the ordinary law; but that is worse than useless at a time when a simple declaration of admixture, obscurely printed on the packet, would amply comply with its requirements, though the mixture contains only 10 per cent of the substance under the name of which it was offered. That such a dilution should be possible with Chicory, and should be carried on to an immense extent, is surely sufficiently destructive to the Coffee trade, but the proposition of the Government would make such practices equally legal with charred cabbage stalks or anything else that was not so heavy as to sink to the bottom of the pot when infused, instead of discolouring the water. Brick-dust must not remain suspended in water long enough, but many forms of clay or stained earth would dissolve and pass muster under the Government proposal, when added to Coffee. Again, the injustice of a scheme is manifest, for, as there is absolutely no machinery for collecting an Excise duty of the sort, the relatively honest trader who paid 2d per lb. duty on the charred cabbage stalks he added to Coffee, would be undersold by his less fastidious neighbour, who could procure ample supplies of the unnutritious but woody stems from his own back garden, without communicating with the Excise. As Mr. H. Pasteur justly observes, in a spirited circular he has just issued on the subject, the public would be horrified were it proposed to legalize the admixture of other leaves with Tea. That commodity is, indeed, specially protected by law, and is inspected by the Customs on import, so that none is allowed to pass into consumption unless it is found to be pure. To be consistent, the Government should repeal that portion of the law, and provide "that a duty of 6d per lb. should be granted to Her Majesty, her heirs, and successors, on all aloe, willow, hawthorn or other leaves, or any other article or substance, intended to be mixed with, or to serve as a substitute for, Tea." The only safeguard that the public would possess in the case of Coffee, would be that when the adulteration became so general that the mixtures are kept in bulk and not in packets or tins, that the Inspectors under the Adulteration of Food Act might from time to time entrap some unwary small tradesman into selling cabbage stalks or date stones under the name of Coffee, without affixing even the vague declaration of admixture, which would protect him under the lax law now in force. Surely such a proposition can only be carried if the Government and the House of Commons are not informed of the effects that would follow its adoption. At any rate, if such a law be passed, it should be accompanied with the provision that the proportions and names of the other substances mixed with Coffee should be declared to the purchaser at the time of sale. Then the levying of the duty upon Coffee substitutes would be fair enough, but in the form now made the proposition would simply add fresh injustice to what the Coffee trade has to

complain of, while it would deliver the defenceless public over to the unstrained mercies of the adulterators.—*Produce Markets' Review.*

Cinchona.—Shaving cinchona bark has been adopted as the mode of harvesting in Darjeeling, having been introduced there by Dr. King after the Java fashion. The trees are said to belooking very well after the operation, and renewal is progressing apace.—*South of India Observer.*

The Total Area of Scotland is about 20,000,000 acres, hardly one quarter of which may be reckoned as arable forest for pasture land, the remainder being occupied by the lakes, rivers, peat-mosses, moorlands, bare rocks, and mountains. It is surprising then to find that against such a vast area of uncultivated ground only 734,490 acres, according to the official returns of 1872, are classed as woodlands.—*Indian Agriculturist.*

Travelling in "New Ceylon."—Our readers will peruse with interst Mr. von Donop's account of his exploration of North Borneo. The "waste land" resources of the country are abundant, and the soil of the higher ranges seems to be especially good. The one great want is population, and this Sir Walter Medhurst is doing his best to supply from China. There are other difficulties to overcome, but we cannot doubt that there is a great and prosperous future for this latest of British settlements in the East.

A new Company, called "The Titaghur Paper Mills Company, Limited" with a capital of R600,000, in shares of R100 each, has been quietly formed and successfully floated in Calcutta in a few days, the whole of the shares being taken up by substantial investors. The Company starts under good prospects of success. It has secured a good site on the river bank at Titaghur at a cheap rate, the machinery has been selected with a view to introducing all the most modern improvements, and the management is in good hands. After completing the necessary buildings it is expected that the Company will be able to commence work after about twelve months.—*Pioneer.*

Cotton Seed Oil and Meal.—"Amongst the latest introductions into the Canadian market," says the Montreal *Gazette*, "are cotton seed oil and meal. The oil is extensively used in the southern and south-western states for culinary purposes, having largely superseded lard and butter. Cotton seed oil is shipped in considerable quantities to Italy and the south of France from whence it is re-shipped to different parts of the world as best table oil The other article above referred to as cotton seed meal, is widely used in the United States, and also in England and Scotland, for feeding beef cattle and milch cows. Over ten thousand tons of this meal were sold last year in the New England States alone, and wherever it has been introduced it has given great satisfaction."—*Rio News.*

The Best Fiber yet used by Mr. Edison for the carbonized arch of his incandescent light is one found by Mr. John C. Branner in Brazil. The plant furnishing this fiber is to be found all through the Amazon valley, and the fiber itself is of exceptional purity, length and toughness. Mr. Edison is delighted with it, and is naturally desirous of securing a permanent supply of it. The difficulty of securing trustworthy laborers for gathering it, the local restrictions, and the certainty that a heavy export duty will at once be imposed upon it, has led to some hesitation in the matter of sending for it. A bamboo fiber was found in Japan which, though inferior to the Brazilian fiber, is easily procured, and is now being used, and will continue to be used until the question of expense in securing the Amazon fiber is settled. Mr. Branner is now engaged in preparing a report of his year's exploration in Brazil.—*Rio News.*

Coffee Culture.—Not long since a friend of mine suggested sowing and forking in green the common *Crotalaria*, and "G. W." long, long ago advocated the growth and digging in of the "Lupine," as practised in Southern Italy.—W. F. Ley.

Agricultural School in Brazil.—The Minister of Agriculture has recommended an appropriation of 480,000 milreis for the founding of six agricultural schools. This, it seems to us, is a very important step, and likely, if the proposal obtains the necessary legislative sanction, to produce valuable results as affecting the material progress of the Empire.—*South American Journal.*

The Coconut a Remedy for Tape-worm.—In the Antilles the coconut is the popular remedy for tape-worm, and its efficacy has been conclusively demonstrated by medical men in Senegal. A coconut is opened, and the almond extracted and scraped. Three hours after its administration a dose of castor oil is given. The worm is expelled in two hours afterwards. In nine cases in which this remedy was tried by a surgeon in Senegal the result was complete.—*Natal Mercury.*

A Russian Tea-dealer at Moscow advertises in the Russian papers as one of his specialities Indian tea. It is described as a "Rose Tea," and the price in English money comes to within a fraction of 5s 4d a pound. As he alludes prominently to the article and recommends the people of Moscow to give a trial to this "new tea," we may conclude that Indian tea is not familiar to the Moscow palate. The name of this enterprizing merchant, it may interest some of our readers to know, is Korestchenko, and his address, Pont des Marechause, Maison Terletsky, Moscow.—*Pioneer.*

The Gum Tree Disease.—With regard to this affection our readers will share our relief at seeing the latest account just received from Abbostford:—"The gum disease seems to be getting better: some red-gums, roses, and tea have quite recovered and are putting on new wood, and altogether, since the fairing up of the weather, the disease seems at a standstill. Last Sunday I saw some Emilina calisaya on———very badly effected, and in some instances quite dead from apparently the same disease, but these plants were on the jungle edge, and at least an eighth of a mile from any blue-gums. There is a small stunted red-gum near them, but it has only a few of its leaves at all bad. I think the wet weather had a great deal to do with the diesease, as all plants (of any description) which did not get too much of it are now throwing out new leaves and buds." The disease may not, therefore, always originate with the gums, although it attacks them with peculiar virulence, that virulence being contagious. We should like to know if the spots have been seen on cinchonas far removed from the possibility of infection from gums.

Artificial Dyes.—The editor of the *Indigo Planters' Gazette*, after quoting notices of various substitutes for indigo, seems inclined to throw up the sponge, writing as follows:—"The energy here displayed by chemists points to a determination on their part to drive the real dye from the market. So long, however, as the prices of these products are not appreciably lower than that of indigo, the latter as a blue, will command the market. Mention has already been made of the requirements which we must fulfil, if we wish to maintain the title of superiority for the natural dye, and to enable us to meet the fluctuations in price of artificial products. The fulfilment of these requirements, however, will be no guarantee against the power and resources of the chemist, who has successively overthrown the madder and cochineal industries. It was said after the introduction of the napthalin dyes, when they were in a state of imperfect development, that they never would be able to throw cochineal and its products out of the market. This opinion has now been changed, for with the better qualities of napthaline colour, the shades can not only be produced just as bright, but even surpassing them. The use of cochineal has therefore decreased considerably."

Correspondence.

To the Editor of the Ceylon Observer.

KOLA NUT AND COCA.

155, Fenchurch Street, London, E.C., July 27th, 1882.

DEAR SIR,—The kola nut (*Cola acuminata*) which I introduced into Ceylon is likely to answer well. The price on the west coast of Africa has now gone up to £100 the ton for the nuts, and a house in London have found that they can use them with advantage and would gladly purchase any that they can find.

The leaves of the *Erythroxylon coca* are now in demand, but your article in the last *Tropical Agriculturist* shews that the leaves very soon lose their active principle. It was for this reason that I have had a preparation made for me in South America from the green leaves, and this has entirely convinced the physicians in the country of the great value of the extract.

As there are plants in the Botanical Gardens in Ceylon, no doubt you will get a supply of seed from them as well as cuttings.—Yours truly,

THOS. CHRISTY.

WHAT AILS OUR (CEYLON) COFFEE TREES ?—No. IV.

SIR,—*Grub* has been declared by some of our planters to have been a more potent factor in the failure of our coffee crops than even the ubiquitous *hemileia* ! Let us then inquire what part it has played of late years in our plantations.

Grub has been known and recognized amongst the enemies of the coffee tree since the earliest infancy of the coffee enterprize. Its incursions, in former times, were confined to particular spots of very small area. Groups of 10 to 100 trees were attacked, and always with fatal effect, on estates in every district of the country. Occasionally several such plots would be attacked simultaneously in different parts of the same estate, and, in such cases, they would occasion serious temporary alarm. The worst of these attacks were, however, of brief duration, and they never proved a permanent discouragement of the enterprize. I am not aware of any instance, until the last few years, in which any breadth of land was so affected. Even now, the cases in which large areas are attacked occur, I believe, in only three of our coffee districts. Elsewhere, so far as my knowledge and observation serve me, the modern incursions continue to be of the same limited extent as formerly ; and they have become, I think, less frequent now than they were 30 years ago.

It is probable that the insects which have committed the recent depredations on such an alarming scale in the districts of Dimbula, Dikoya and Maskelya are not of the same species as those formerly known, and which continue occasionally to visit the other districts. Their attacks differ, not only in extending over vastly larger areas, and enduring for a much longer period, but they are fortunately much less fatal. The attacks of our old enemy were generally discovered and recognized by the sudden death of their earliest victims ; whereas the grub which infests the large young districts specified, rarely kills the trees outright, and never with the suddenness which characterizes attacks of grub elsewhere. Nevertheless the formidable nature of its depredations places it in the very foremost rank of the enemies of our enterprize. It has undoubtedly aggravated the evils of the decade to a most serious extent ; still the fact must not be overlooked that even in the districts where it has committed such havoc the infertility of the coffee trees has not been confined to the infected parts, but has manifested itself universally, and has been subject in these districts, as elsewhere, only to the same kind and degree of *exception* as has occurred so unaccountably in the oldest and worst districts !

A local expert is of opinion that the grub which has infested these young districts has been attracted by a fungus on the roots of the trees, which, if correct, would prove the pest to be of a secondary or consequential character. In any case, however, there is no such coincidence between the attacks of grub and the infertility of our coffee trees, as would establish the relation of cause and effect. It is impossible therefore that grub can have originated the universal failure of the fruit-bearing power of our coffee trees, or have had any primary connexion therewith.

The *clearing of forest land* has, at one time or other, been brought forward, in almost every country where it has been extensively carried out, as a sufficient reason to account for almost every evil that has afterwards beset the agriculture of those countries ! And it is now adduced as the primary cause of the ailment of our coffee trees ! Needs must, therefore, that it should take its place along with other alleged originators of our discomfiture in this discussion. It is a vexed question, and one which crops up continually in agricultural circles, with its youth renewed for each fresh advent ! It seems always at hand ready to answer for anything or everything that concerns the welfare or the discouragement, alike, of the agriculturist. It meets you at every turn of your quest, whether you be in search of an old friend that has disappeared, or a new enemy that has entered the field !

When God sent man upon the earth, He commanded him to "subdue and replenish" it. This command, if it had any meaning at all, signified that man was to convert it to his use. Accordingly, man has cleared away the noxious and unproductive vegetation that cumbered the ground, and has *replenished*, not *denuded*, it ; turning its wastes into smiling fields, and re-clothing its unwholesome jungles with fruitful and salubrious vegetation ! Wherever man, in obedience to his divine mission, has subdued and replenished the earth, fertility, salubrity and prosperity have rewarded his labours, and wasteful growths, deadly climates and barrenness linger still in the yet unsubdued and unreplenished wilds of the world. The statement made by a correspondent, that a long list of countries, which he enumerates, have been ruined by the mere clearing of their forests, is opposed to world-wide experience, to the history of the human race, and to the order of Providence. If, indeed, they have been ruined, their ruin cannot be attributed to a cause which, in all the range of human experience, has proved to be *beneficent* alike in its operation and its origin. Let those who make such statements prove them. As for me, I repudiate them as contrary to commonsense, and dishonouring to divine authority.

It is not denied that climates have changed, are changing, and must ever change. Change is *life* ; stagnation *death*. The maintenance of life demands unceasing change, and when the cycle of *life-changes* ceases, a cycle of corruptive changes inaugurates new life in other forms. So, *cosmic* life maintains itself by change incessant, but ever obedient to laws ordained by Him who bade his creature, man, microcosm, subdue and replenish His earth. There is no conflict in His laws, and though their harmony may not be evident to our poor vision he would be a fool indeed who would distrust God's wisdom on no higher testimony than that of his own judgment. The arid deserts of the earth, not less than its most fertile plains, owe their condition to meteorological laws, wholly independent of the sandy carpet of the one, as of the luxuriant herbage of the other,

Probably the result most generally believed, and most frequently reiterated, as attributable to the so-called *denudation* of forests, is *deficient rainfall.* Whenever a failure in the rainfall happens, it is straightway laid to this account; and even should it follow upon a period of excessive rain (which is left to account for itself as best it may) the felling of the forests is denounced by almost common consent! Yet, what a strange inversion of cause and effect, or jumbling of them together, is here involved! Either the forests bring the rain, or the rain brings the forests. Which is it? If rain preceded the forests then it needs them not. We may cut them down. Rain came at first without their invitation, and can remain without their aid. But, if the forests preceded the rain, and drew the reluctant waters from the firmament, then the forests originally grew without the heaven-born element, which fell *superfluous*, a puzzle to mankind. In this connexion it might be asked what has brought us this year's ceaseless downpour? If the forests have anything to do with it, there would seem to be still enough left of them, and to spare.

But the question for us in this discussion is to ascertain whether denudation (improperly so-called) of the forests can in any way have contributed to the infertility of which we are seeking the origin.

There is certainly no evidence afforded by our experience in this island that the conversion of the forests to the cultivation of useful products has been injurious either to the health of man or the growth of vegetation. So far as our knowledge avails us, the replenishing of the land, with fruit-bearing, useful vegetation in place of that which was useless and malarious has proved an unmitigated blessing. Theorists may speculate upon consequences of their own imagining; but the facts of our knowledge, the evidence of our experience is that here, as elsewhere, man has done well to subdue and replenish the earth. If any injurious consequences have followed the progress of this work, it is more reasonable to attribute it to the unwitting breach of some law we have failed to recognize, than to indulge in speculations that impugn the wisdom and goodness of God. When the Israelites took possession of the promised land, and neglected to first drive out the Canaanites they suffered bitterly for their disobedience of that part of the divine command. In like manner, we may suffer if, in obeying one law, we overlook another. If, therefore, it could be *proved* that we have suffered by clearing so much forest, it would behove us rather to search for laws we may have broken, than to *assume* that our misfortune is due to our having obeyed the dictates of the reason and ordinance of God. In fact, the whole aim of our discussing what ails our coffee trees is to dispel the illusions and speculations which have so long diverted our attention, and stood between us and the truth regarding the origin of our misfortune. Instead of resting satisfied with speculative causes, which prove, on examination, to be wholly irrelevant, or utterly insufficient, we should boldly cast them aside, and clear the way for efforts of a more logical and practical nature.

Already, in discussing "abnormal seasons," it has been shown that whatever may have been of abnormal character in the seasons of the last decade, there is no correspondence between the phenomena of infertility and those of season. We need not therefore further discuss the question of forest clearing in its supposed relation to the seasons. Since the letter on that subject was published some valuable contributions in regard to season have appeared. These will be reviewed hereafter, when this correspondence closes. In the meantime, it may be pointed out that evidence which would prove a change of seasons for 20 years past has no relation to results exclusively confined to the last ten!

The only practical and reliable test which our pest experience affords us the means of applying in order to determine the actual effect the felling of our forests may have had on the loss of the fruit-bearing power of our coffee trees seems to me to be, by referring to those estates, or groups of estates of which some yet remain, where the surrounding indigenous jungle continues almost intact. Whatever ill results overclearance may be capable of producing, its effects should be minimized if not wholly absent, in the estates so situated. Looking, then, to these outliers, far removed from extensive forest "denudation," and still enjoying whatever advantage the proximity of predominant forest may possess, do we find them exempt from the evil of infertility, either wholly or in any appreciable degree? Or have they shared to its full extent the common misfortune? The answer is conclusive. Neither the numerous small plots of native coffee, which are embedded in overwhelming tracts of larger growth, nor yet the more extensive fields of cultivated coffee, which are still surrounded by indigenous jungles, afford any evidence in favour of the idea, that the evil we deplore, either originated by, or has any direct relation to, the felling of our forests. Possibly the extensive and sweeping clearance of jungle in the young districts may have favoured, or even originated, the attacks of *grub*, from which they have suffered so much; but it is no part of our task to trace the origin of *grub*, as it has been shown to have no relevancy to our discussion. Sufficient is it for our purpose to show that the clearance of our forests, whether directly by its own influence, or indirectly through its supposed effect on season, cannot have originated the universal loss of fruit-bearing power of our coffee trees. Our misfortune neither synchronizes with such clearance of forest, nor has any recognizable relation therewith, either direct or consequential. W.

COFFEE-PLANTING IN THE BAMBOO DISTRICTS OF COORG.

Amatty, Coorg, 7th Aug. 1882.

Dear Sir,—In my letter of 29th June, which you were good enough to publish, and also to notice editorially, I regret that there was one paragraph—beginning, "In the bamboo districts," &c.—which hardly expresses what was meant. I intended to say that, notwithstanding the great drawbacks caused by the dry climate of the bamboo districts, planters preferred casting in their lot in them. But, finding from experience that coffee cultivation would not pay without having it grown under shade, this was made a *sine qua non*, and hence shading was studied closely and treated with great attention. It was found easier to grow the suitable shade in the bamboo districts than in the forest. Consequently land in the former went up in value, while, in the latter, the demand ceased altogether. Another slight mistake I notice, too: instead of a considerable *series* of experience, &c., please read *period.*—Yours faithfully,

A BAMBOO PLANTER.

CAPT. COX'S WYNAAD LEDGERS.

Cherambadi, Aug. 17th, 1882.

Dear Sir,—I must apologize for not sooner giving you the information asked for in your footnote to my letter of the 10th ultimo, regarding the age of the trees, bark analyses of which I sent you. Six of them were planted in the field in 1874, thus making them eight years old now. The remaining one, No. 6, yielding 7·20 crys. sul. quinine, is a six-year old tree. At the same age, it may shew as good results as the others.—Yours faithfully,

PERCY GUARD.

THE VALUE OF CINCHONA TREES.

Haputale, 23rd August 1882.

Sir,—The *Observer* of 14th August 1879 had the following as value of cinchona trees :—

Age.	Succirubra.	Officinalis.	Ledgeriana.
2 years	R 1 ₱ tree	R 1 ₱ tree	R 1½ ₱ tree
4 ,,	,, 3 ,,	,, 3 ,,	,, 4 ,,
6 ,,	,, 7 ,,	,, 7 ,,	,, 7 ,,
8 ,,	,, 10 ,,	,, 12 ,,	,, 15 ,,
10 ,,	,, 15 ,,	,, 18 ,,	,, 22 ,,

Do you consider the value holds ? and if it does, does it mean the average to be obtained for trees uprooted at four years old and upwards ? or are the values given, those for valuation of an estate and so including prospective enhancement of value ?

I wish to know the probable returns from uprooting. It is likely the value of trees for destruction may be greater at the small ages in the Kandyan districts than in our dry Uva climate ? Can any of your correspondents say as to this ?—Your truly,

S. T. R.

[See our remarks, page 303.—Ed.]

COFFEE CULTURE :—SECONDARY AGENCIES AND THE FIRST CAUSE.

26th August 1882.

Sir,—Loss of nitrates, abnormal seasons, grub, and leaf-disease, have, one and all, been suggested as causes of our staple's present ailment. Per contra "W." lays down that "it is God that giveth the increase."

Now, sir, I am all rapt attention when "W." writes on the basis of his broad scientific knowledge, and the vast observation he has brought to swell the volume of that knowledge but I must regret to see him shuffle out of his position of advocate for wider scientific research as accessory to our present system of cultivation with a vote of thanks to his God for the increase (good crops) He sees fit to withhold just now. I presume "W." did not wish us to infer, by his writing "first cause" with small initials, that we should go to the devil for the *raison d'être* of short crops. But this is what we must conclude from his letter. The less religion is mixed up with manure in writing on coffee, the better able shall we be to arrive at some means of opposition to "the slings and arrows" to which "outrageous fortune" now treats us. I would ask "W." to reflect for a moment on the large number of diseases common to the human system which scientific enquiry has brought within the last half-century into the category of curable complaints from that of "visitations of God."

The analogy existing between the animal and vegetable kingdoms, in relation to nutrition, reproduction and decay, becomes clearer and clearer as the years roll on. In this connection let us take, as types of these two kingdoms respectively, a lovely girl and a fine coffee bush. Without going right along their several roads with them, we shall find, I think, that the ruin of each is traceable to *exposure*. This is my present opinion with regard to coffee's "wretched fall," and, if you will bear with me, I will endeavour to show that your correspondents "W.," "W. D. B." and "X." all point to this without directly naming the name.

"X." flings at our heads long columns, in perusal of which the eye wearies, as with a conventional wall-paper in a sick-room at the frequent repetition of "nitrates" and "nitrification." He means evidently that to run our rainfall off, as the present system of draining causes it to run, is to lose some very valuable plant-food, viz. *nitrates*. At this up jumps "W. D. B.," and says he :—"Why, my good sir, it 's this very abundance of nitrates that we do *not* want. Man alive, can't you see the trees are always making wood and does n't that argue superfluity of nitrates ? Between you and me, my friend, I think it 's just *abnormal seasons* that are at the bottom of these short crops." Here "W." chimes in with his 'want to know" what "W. D. B." may mean by 'season" and "abnormal," with a hair-splitting precision worthy of Plato. Given these two definitions, and he thinks we may start fair. Nevertheless, he himself opines that the reign of law does not apply to seasons in Ceylon and that the word "monsoon" is merely a conversation-toy meaningless, the which I think a little, just a little irreverent on his part. Notwithstanding all which he holds that fine weather in the blossoming months, and again at that season of the year which we, in our folly, have deemed the between-monsoons, may be taken as a ground for hopes of a good crop, in which sentiment he and "W. D. B." are really at one.

"W." has told us that in early days estates were never opened without a liberal allowance of standing-jungle breakwinds. *Nous avons changé tout cela* : nowadays a belt is the exception ; and herein I think, lies the key to the mystery under discussion. "W." will not deny that coffee which suffers the direct influence of wind is now everywhere as shuck as shuck can be, nor that hollows which enjoy, more or less, immunity from wind are looking as hearty as ever, nor that in these same hollows both from their position and the shade afforded by thick foliage, the ground is ever moist, nor that on exposed fields the wind and sun absorb all moisture almost as it falls. From these postulates the conclusion is not difficult that it is moisture that we require ; and that it is *wind* which counteracts the benefits intended for us in copious rainfall must be admitted, as surely as that a too general forest denudation has opened the doors to this wind. So that "X." is probably correct in his "nitrates" theory, and "W. D. B." not far out in his "abnormal seasons" conjecture. "W." will, of course, not allow these remarks to pass unchallenged. Indeed, he has already raised objections to any such possible conclusion as the above by his notice of those patchy fields, wherein, he thinks, lies buried the key with the aid of which we may let ourselves out of this prisonhouse of doubt. Can "W." point to any large hill-side, where holes cut five (5) feet deep would reveal homogeneous surface and subsoils ? May it not be that where the coffee is fine the soil is just retentive enough, and *vice versa* ? If I am right, deep water-holes among the shuck coffee might be our remedy. I am speaking here, as I think "W." was, of fields of coffee which only feel the wind indirectly, or scarcely at all.

In closing this too long letter, I would ask you to credit me with *bona fides* in any writing of mine, and, if my pen at times runs off into cynical remarks to believe that these are not prompted by personal feelings, or that your correspondent "only does it to annoy, because he knows it teases." I ask this, as I see that your footnote to my last led some to misconstrue the spirit in which it was written.—Faithfully yours,

P. T. L.

WHAT AILS OUR (CEYLON) COFFEE TREES ?—No. V.

Sir,—Amongst the many causes which have been suggested from time to time as having originated the infertility of our coffee trees, one that has found a certain amount of favour is our "*too exclusive cultivation of the one product*," coffee.

As to the *policy* of our having committed our interests so exclusively to one staple, there is, I suppose, but one opinion. It must be generally conceded that, if we had devoted our attention to other products before our coffee failed, we should not now have been

so ruinously affected. General as has been the discouragement of agriculture in almost all countries during the last decade, some products have escaped, or have at least enjoyed *comparative* immunity from the infliction which has smitten our coffee. If, therefore, our estates had been devoted to several, instead of being exclusively occupied with one product, we might have enjoyed at least a partial prosperity, and should not have suffered such total discomfiture.

But it is not merely as a matter of *policy* that our *too exclusive cultivation* of one product has been condemned. It is adduced as a cause of the prevailing loss of fruit-bearing power of our coffee trees! In what manner this has been brought about is not stated. The authors of this doctrine do not appear to have considered it necessary to connect the means with the end. It has been expected to carry conviction and to need no enforcement. A very sagacious planter of my acquaintance furnishes the only argument I have ever heard advanced in its favour. This gentleman has very consistently, and for several years past, divided his attention upon several products; and has therefore profited substantially by his belief in the hypothesis that a country can only produce a certain quantity of any one product. Ceylon, for example, on his theory, can only yield, say, a million cwts. Beyond this stipulated natural capability it would, he believes, be impossible to stretch the power of the country to produce coffee. Even though the whole island were planted up with coffee it could not yield more than the prescribed million cwts.! This theory seems to be based upon the opposition that *something* necessary for the production of coffee has been dealt out to Ceylon in certain measure, and that we have overdrawn the account! It reminds me that I once heard from a highly-intelligent and well-informed friend, who had resided in a sugar-growing country, that, after the cultivation there had extended till the crop attained an aggregate of, say, half-a-million hhds., all attempts to raise the crop beyond that quantity failed entirely, though the area of cultivation was more than doubled! It is not possible to confute a theory of this kind. It *might* indeed be true! If, however, for the sake of argument, we were to accept this hypothesis, it would not fit our case. Had all our subsequent crops, after we had reached our million *allowance*, continued to average about that quantity, irrespective of largely-extended area of cultivation, we might have inquired further about the theory; but it fails to account for the sudden change which came over our coffee trees in 1871, and for the reduction of our total crop during the decade to a quarter of the prescribed allowance. Why this curtailment of our credit by 74 per cent? This is precisely what we want to know, and this theory does not help us! Indeed, it would hardly have been worth mention, except to show how unsatisfying are all attempts yet made to account for the ailment of our trees and to what extremities we are reduced to find an adequate originating cause!

Then there are those, a goodly number, who lay the whole blame of our misfortune on *inbreeding!* We are rightly served, say they, for having neglected to import fresh seed. We really cannot omit to notice this complaint.

The degenerative tendency of successive crops from seed grown on the same soil is on all hands admitted. If, therefore, we could be convicted of having made so grievous a mistake we should deserve blame, twhether the evils we suffer were or were not the penalty of our fault. But is it a *fact* that we have trained *successive* crops by sowing and resowing the seed so raised in the same soil?

Certainly not. The accusation originates with a total misapplication of principle. The theory applies to *annual* plants, raised from year to year, through many successive generations, from seeds sown and resown on the same lands on which they were grown; and is not applicable to perennial trees; unless to a very slight degree. We have yet amongst our plantations the very identical plants, living and fruiting which were produced from the first imported seed! We are even yet sowing the seed from these very trees, and are in so far, in the very first generation of direct descent from the primevals! Possibly some of the later school of planters may have been less careful regarding the sources from which they have derived their seed and plants, but formerly the selection of seed and the sources from whence it came were habitually regarded as of *primary importance*. The same care is still exercised by many at least of the modern school, if indeed it has been wholly neglected by any. The seed from the older plantations, whose produce had an established character in the London market, was always in high request, and continues to be so still. It follows that a very large proportion of our coffee trees are but first descendants from the trees of imported seed! Moreover, within my own knowledge planters have imported seed from Mocha and elsewhere. Amongst my earliest recollections relevant to this subject was a prediction of an old planter about 1847 regarding two contiguous estates, of which he prognosticated that one would be a flourishing property after the other should have died out. The prophecy was based on the fact that one had been planted from the nursery and the other from the villages. I have lived to see that prediction verified. Village plants were in those days strongly denounced, and few planters would then have incurred the odium of resorting to such a source for their supply of plants.

It follows from the foregoing scrap of history that, even supposing some of the younger estates may have been grown from seed which had passed through two or three descents; and, granting that here and there some of the older fields were planted from native seed, *inbreeding* to this limited extent, even if the term could with any propriety be applied to the case, could not account for the sudden change of our prospects in 1871, nor for the universal infliction from which we are now suffering. Still, it would be a useful lesson to some planters of this present period, if they could see the fastidious care with which planters of old selected their plants and watched their coolies planting them. Had the same discrimination and care been exercised in selecting and planting cinchona as were observed in regard to our oldest coffee plantations, the result would very amply have repaid the pains and sacrifice they would have entailed. It is probably to this care and personal supervision that we may attribute the fine luxuriant fields of coffee still extant on our oldest estates. But alas! these have shared the same fate as the younger generations, and we are therefore forced to search for causes more applicable than *inbreeding* to our case, if we are to account satisfactorily for the origin of our present misfortune.

Imperfect fertilization ascribed to the supposed decrease in the number of bees about the estates, has been suggested as a possible cause of failure of fruit. And, though I have not heard of many disciples of this doctrine, it is by no means unworthy of notice, not only because of its bearing on the natural method of fertilization of coffee blossom, but because it has an interesting relation to recent unfavourable blossoming seasons. The fact is that, owing to the relative position of anthers and stigma of the coffee flower, no foreign agency whatever seems to be necessary to the fertilizing process. Nay, indeed, is it requisite for the purpose of impregnation that the flower should ever open. This fact renders the process of hybridization and crossing in the case of the coffee plant extremely

difficult, and sometimes precludes altogether the possibility of such an operation. It is often the case that some pollen matures and impregnates the stigma, with which the anthers are in close contact *in the bud*, before the flower opens. Indeed, cases have occurred, and I believe not unfrequently, where fair crops have been produced without any blossom ever having blown. Notably, about 20 years ago, several estates in my knowledge failed to blossom. The spike grew to be about a third of an inch long, and then, in planters' parlance, "turned to brush" at that stage without acquiring so much as the size of decent spike. Yet crop ensued on each of these estates, and, though it came in such a questionable way and was by no means abundant, the quality of the bean was apparently unimpaired, and betrayed no such sign of deficient stamina as to raise doubt of its being sufficiently fertilized. The unfavourable weather of that blossoming season seems to have had no effect on the productive power of the trees, which yielded their crop notwithstanding the disadvantage of so imperfect a blossom! Have we not here a proof of some new cause of infertility to account for the different behaviour of our trees in these days as compared with what they proved themselves capable of doing formerly, even when they had to contend against such adverse influences. Today we are not sure of a crop, even though the spike pass through all its normal stages and develope into fine, healthy-looking flower. Would that we could discover the secret of this fatal deficiency. But, be it what it may, it evidently does not consist in, or depend upon, the agency of *insect fertilization*.

Careful analysis of all the theories which have been suggested to account for the loss of fruit-bearing power in our coffee trees seems to show that we are yet entirely in the dark both as to the nature and origin of the malady. Our inquiries seem, in fact, to have been pursued in wrong directions. We have been seeking for the cause of a world-wide discouragement of agricultural enterprize in strictly local influences. Our researches into the cause of a sickness which affects a whole race have been restricted to the study of a particular disease of a single family. Had the same industry and perseverance with which we have studied local coffee leaf-disease been directed to logical inquiry in the wider domain of the agriculture of the world, we should have been saved much futile effort, and might possibly have acquired useful, practical knowledge. A review of our past efforts seems to indicate that the true nature and origin of our misfortune should be sought by inquiry into the various forms in which discouragement has smitten the agriculture of other countries beside Ceylon, and into the degrees in which other branches of the vegetable kingdom have been affected here and elsewhere. Should our researches fail to reveal the real cause, which may probably lie outside the boundaries of our present knowledge, they might nevertheless show the limits of its sphere of operation; and, more important still, they might unfold to our view the nature of those counteracting agencies which are so strikingly exhibited in the strange exceptions we see around us to the general rule of infertility. The facts that discouragement has not extended equally to all countries, though none would seem to have been totally exempt; that all classes of vegetation have not been affected in the same manner and degrees; and that some branches of agriculture have altogether escaped the malific influence which has so severely smitten others, are all facts full of significance, and therefore full of promise to patient, intelligent research.

The imperfect review of our past enquiries into the cause of the misfortune which has befallen our staple enterprize, which this letter closes, is submitted to my fellow-planters in hope that they may add their contributions to the common cause. Before suggesting more particularly the course of enquiry which seems to me most promising, I wait for such aid as their criticism and remarks may afford. W.

IN-AND-IN BREEDING, &c.

Dear Sir,—With respect to in-and-in breeding I think the general idea is that *any peculiar trait* of individuals or races of men or animals is maintained by that means. It narrows rather than widens the intellect. The race-horse is kept a race-horse thereby. Extraneous influence destroys this speciality of character. The Jews, who were a peculiar people, went in largely for cousin marriages, and this habit is often given as one cause of their dissimilarity to all other people. It has also I believe been proved by breeders of fox-hounds, harriers, beagles and such like uniform creatures that suddenly introduced extraneous blood has broken up the beautiful equality of style and uniformity in their mode of hunting, and what has been harmony has become discord and confusion. The action of the extraneous blood is, however, I believe, said to be more potent but less plastic in its progeny: creatures are often larger, but irregular, and scarcely so symmetrical and beautiful. A far removed strain in horses and dogs does not produce progeny so true of type and so amenable in the hands of man, and whip-cord is thereby often more in request. Among plants, true type and character cannot be assured, if kindred and often hardier species of the same are growing near by, and the very peculiarities you may require may thereby be eliminated. I write this in reply to rather an imperfect representation of the *Queenslander* in the *Observer*. In all cases of in-and-in breeding, I think it can be clearly proved that it retains peculiarities. Intellectually in man it would act the same, but it has been argued that the mind of man will not bear a strain in only one direction without injury.* This I can say nothing about: it is too delicate a subject. All our most useful domestic animals, all our prize oxen, horses, poultry and everything else of special eminence is the result of breeding-in. Once allow the hardier and rougher outsider into your flock, and you may have a creature better able to fight the battle of nature, but as an economical creature for the use of man from generation to generation you must return to the flock and adopt what, if inquiries are made, will prove to be breeding from very close relationship. W. F. L.

THE NORTH TRAVANCORE LAND SOCIETY, AND THE PROSPECTS OF THE KANNAN DEVAN HILL DISTRICTS WITH CINCHONA AND TEA.

Sir,—About 18 months ago, you inserted an article in your paper which I wrote to the *Field* under the *nome de plume* of "Staplegrove," descriptive of the country owned by the above Society, and you advised planters to wait and see what progress would be made in planting by the Society before they thought of investing in land in the new district. I am now on another visit to the Kannan Devan Hills, and I think that a brief account of the progress of the enterprize may be not unwelcome to the planting community, if you will kindly give it a place in your journal.

It will be remembered that I stated, in the article on the "Kannan Devan Hills" alluded to above, that the country seems hardly to have been visited by any European, until Mr. Munro, the well-known Peermaad planter, penetrated into it about 20 years ago, and directed attention to it in a pamphlet entitled "A Report

* What does Galton say in his book on the subject?—Ed.

on the High Ranges of Travancore." For several years afterwards he and other sportsmen were in the habit of resorting to these high ranges for bison and ibex shooting, which was, and is still, to be had there in great excellence. So it came to pass, as has been the case with so many planting districts in the world, that the lands that attracted the sportsman by-and-bye came to be desired by the planter, who now hangs up his rifle and telescope in the corner of his bungalow which he has built among his cinchonas and his tea bushes.

The salubrity of the tract made it desirable as a place of abode. Twenty years ago, no one thought about condamineas and pubescens, and the tea industry was at a discount in Indio. So these high ranges, with their magnificent forests, were let alone as being at too high an elevation for coffee, and it was not until the cinchona mania set in strong (about 5 or 6 years ago) that the forests at 6,000 and 7,000 feet were sought after.

The tract of uplands known as the Kannan Devan Hills, now the property of the North Travancore Land Society, lies between the Anaimali Hills of Coimbatore and the Pulney Hills of Madura, connecting those two ranges, like an elbow-joint, in uninterrupted sequence of elevation. Thus, a charming expedition can be made from Kodekanal on the latter mountains along a mountain path into the Kannan Devans, as far as the elbow-joint at Munaar, and thence north into Michaels valley in the Coimbatore Anaimalais, descending to Pollachy, which is within a night's journey of the Madras railway. The expedition from Kodekanal to Michael's Valley could be done in about ten days' easy marching. February is the time to choose. The whole journey lies along grassy plateaux and valleys and over shoulders of hills, with hardly an inch of jungle and between 5,000 and 7,000 feet above sea-level. The cold is considerable at night, and frost could be found in many of the valleys.

The possessions of the Society, including forest and grass land, rocks and mountains, are taken to exceed 100,000 acres in extent, and there is, perhaps, 30,000 acres of virgin forest within the boundaries. On the west, the forest runs from 5,000 feet down to 750 feet above sea-level, and it is on that side unbroken in extent, the rainfall there being upwards of 120 inches per annum. The further east we go, the higher the country becomes, culminating in several lofty mountains over 8,000 feet high, the slopes and valleys of which are now clothed with dense sholas, now open grass, according to the exposure, and a shelter from the S. W. & N. E. monsoons—120 inches, 100 inches, 80 inches—marking the gradual arrest of the western monsoon as we get east of those giant hills which bar its advance. Among these hills, on the plateaux, in and along the elevated valleys, lie the sources of a branch of the Roryar and of the Amrâvati, a feeder of the Kâvari. The plateaux, where the Amrâvati rises, is within the Society's boundary. General Douglas Hamilton first visited and described this place. This is a curious place—a large and wide plateau of grassy downs, some miles in area, 7,000 feet above sea level; in the midst of this is a lagoon, fed by the drainage of the swamps at the foot of the downs. This lagoon is about a mile long, and several feet deep, full of the purest water in the world, banked back by a ledge of rock over which the excess water pours into another tortuous lagoon, which is also banked up by another ledge of rock, down over which the water pours in a cascade several hundred feet deep into Turner's Valley. There it pursues its course, meandering along a channel fringed with the most lovely rhododendron trees, which in January are in full bloom, till it falls over into the Palliar Valley and then into Anjinad and so on to the Coimbatore district. Some attention has recently been directed to a hill-station in South Travancore, which may be good enough in itself, but for a true hill sanatarium the place is Hamilton plateau. Without any doubt, it is the finest place in South India for a hilltown, and, if the Maharaja of Travancore desires to found such a town, I hope he will call for information concerning Hamilton plateau before he commits himself to some contracted minor elevation on the Asamboos. Its extent, its scenery, the lovely walks that could be constructed to the top of Anaminudi 8,800 feet, to the top of Kanthamallai 8,100 feet, Vagawunai 8,000 feet, with its lagoons, its waterfalls, its rhododendrons, wanting but a few plantations of trees such as have been successful on the Neilgheries to screen it during the S. W. monsoon, are certain to ensure its being taken up some day when it becomes accessible to the arteries of communication. The Society, however, have fixed their headquarters at Devicolum on the southern edge of their territory, because of its proximity to the plains of the Madura district, with which it is connected by a bridle-path 20 miles long to the town of Bodenaiknur 16 miles west of Periacolum, the headquarters of a Tahsildar and 26 miles from the S. I. R. station of Ammanaiknur, which is a night's run from Tuticorin.

Devicolum, where there is a post-office, is 6,000 feet above sea-level, and here the Society have clearings over 300 acres in extent, and within 2 and 3 miles private estates are being opened, all of cinchona officinalis raised from Dodabetta seed. To those who understand such matters, it will be sufficient to say that the two-year old cinchona is from 5 feet to 8 feet high and the same number of inches in circumference, while one-year old plants are 3 feet and 4 feet. The total number planted out in the clearings must be over 7 lacs: 1½ lacs 2-year old, 2½ lacs 1-year old and 3 lacs just planted. Here also are a few of the so-called *pubescens* which rear their heads high above their *condamnean* brethren. There seems to be no difficulty about coolies; kanganies come up from Madura and Tinnevelly with gangs; contractors for felling and picking are abundant and not more evasive than the race is in other centres of planting enterprize; and carpenters find their way across from Cochin and stay up readily enough till the monsoon bursts. Virgin forest land in this Devicolum district is now selling at 30 to 40 rupees an acre.

Besides the Devicolum district there are three others where operations have been commenced either by the Society or by private planters. The three districts are Alanjimed on the east, adjoining the Pulneys, where there is a large tract of forest some 6,000 to 7,000 feet high.

The rainfall is somewhat less at Alanjimed than at Devicolum, but the fine mountain Karrincolum over 8,000 feet high arrests a great deal of moisture-laden clouds, which condenses into rain along its slopes, and has caused a very excellent forest growth. There is a fine plateau on the summit of this mountain, higher I suspect than any plateau of extent in South India. It abounds with water, two or three very considerable streams falling down over its sides into the valleys below. It is well worth visiting, and occasionally a good saddle-back may be found along with the herd of doe ibex which the Society rigorously preserve on this mountain.

From Devicolum an excellent bridle-path some miles long leads to Munaar, where the Society have opened 170 acres of forest land in tea, coffee and cinchona. This is all two years old. The cinchona (officinalis) is of good growth, and there is a promising show of berries in the coffee bushes, while the tea bushes are already yielding a virgin crop. The elevation on this side is 4,800 feet and here the unbroken forest commences which clothes the whole western edge of the Kannan Devans. The cardamom is indigen-

ous here, and the Society, I believe, intend to bring a tract under cultivation when they find themselves able to do so But the Travancore Government claim a considerable share of this crop by virtue of a monopoly they exercise, and it is doubtful whether systematic cultivation with European superintendence would under these circumstances leave a large margin for profit. But this Munaar country is no doubt the place for tea, and not only within the Society's boundaries, but all along in the adjacent country known as the Chengamunâd forests, comprizing probably 100,000 acres of virgin forest, I do not suppose there is any better tea land in the world than this, and, if the Travancore sovereign were disposed to have it opened out, I believe it would bring enormous wealth to his country. Steamers would run from Cochin straight to London, and this port is no great distance from the country I am writing about. The Society is selling land here at R25 an acre.

Starting again from Devicolum, a rough path, 14 miles, leads to the Talleai district, elevation 4,000 feet and upwards, where, as some critics contend, the finest land is to be found. This is a deep valley facing the east, protected on the west by a semicircular range of mountains 7,000 to 8,000 feet high. The Society have opened 300 acres here, and a private company is opening up a block, while applications for other blocks are daily coming in. The price of land here is stated to be R30 an acre. A path has been opened out from Talliar to the Coimbatore district, distant some 30 miles, and this is a great convenience for planters in this district, as it obviates a long portage of goods across the hills from Devicolum. It requires but a very little improvement on the road to enable carts to come within fifteen miles of the Talliar valley.

As a new planting district, the Kannan Devan hills merit the attention of planters. It certainly possesses many advantages over such as Burma, Borneo, and the Straits. Labour is cheap and inexhaustible; the proximity of the districts of Madura and Tinnevelly guarantee this. The suitability of the soil for planters' products is established by the success of the Society's openings. The salubrity of the climate can be vouched for by the manager, Mr. A. W. Turner of Devicolum, who has not had any fever himself, nor have his European assistants had it, nor yet his coolies, and he has now been there upwards of four years. In Talliar, however, there is some suspicion of fever, as you get low down. On the other hand roads are not in existence and no cart can yet get into the country. Consequently there is some difficulty about supplies; land is getting scarce, therefore dearer, every year, but there is no trouble or delay about getting a title which can be procured at the Society's office at Devicolum.

STAPLEGROVE.

"TRAVELLING IN NEW CEYLON" (NORTH BORNEO): BY AN EX-CEYLON PLANTER.

Pappar, June 20th, 1882.

Dear Sir,—A short account of a trip I have just returned from, inland, may be amusing to your readers, as it will give them some idea of the inland of Borneo, which at present is very little known. I left here in a boat with 20 natives as guides and baggage-carriers, and was paddled up this river, which is very pretty, and its banks will no doubt before long be more thickly populated than they are at present. Some distance up the river was free of all obstacles, but shortly after passing a small village called Conquot the rapids began, which made our passage rather slow. I was informed that a chief called Tahan lived here whom I was anxious to see, he having been Mr. Dobree's pilot about this part of the country; however I thought it better to push on and make his acquaintance on my return. We reached our destination about 4 o'clock—earlier than I anticipated—and found two little huts erected by Government in which we put up for the night. Early next morning we commenced our march inland, our track taking us through chena, but there were no signs of inhabitants. After crossing several rivers we arrived at the foot of the mountain range and put up in a comfortable little hut erected a few days previously, which kept us quite dry and snug, while it rained cats and dogs outside. Next day we commenced our ascent of the mountain range, which was rather hard work to the men who were carrying loads. We, however, reached the top 4,500 and descended to 2,500 on the other side, where we made a little leaf hut beside a ravine and stopped that night. Next morning I woke feeling rather cold, and found a heavy dew falling, and was glad to be on the move. The soil in parts was very rich and generally of a fair nature. Arrived at a river below I was able to obtain a view of the land we had been descending through, and noticed several small native clearings, which I had not previously seen. I met a Dusun on his way to Pappar with a load of gutta, and was much interested in the coat he wore, it being made out of the bark of a certain tree. It appeared strong but coarse. It would, I was informed, last for 5 years, but did not stand washing. He was smoking a pipe which he made himself, and his tobacco did not smell or look at all bad. From the river 2,200 we began to ascend, and our path during the day was mostly at that elevation, but towards evening we descended and put up in a native house, the elevation being 2,650. The roof I noticed was made of split bamboo put on in the same fashion as tiles and appeared to act very well. Previous to arriving at the house I had noticed a small forge where two men were busy making tools out of old iron. The owner of the house received us most kindly. These houses are generally constructed with an enclosed verandah, from which there are doors leading into the several compartments. We all made ourselves comfortable in the verandah, there being the usual curiosity among the occupants to see the white man who had been the first to visit their village. Next morning we were delayed in starting, waiting for guides; these men were not, however, of much use to us, as the next village they came to they wanted to eat a meal, but, as I had already been delayed an hour, I decided to leave them and push on by ourselves. A rather difficult river had to be crossed, and then our track led for some distance along its banks. I was rather startled, when walking through the chena which lined the banks, to see my men all of a sudden going down like ninepins in front of me. I soon saw the cause: a huge wild buffalo had charged them, but fortunately changed his course before coming to me. A short time after we came across a party of native sportsmen, who, it appeared, were on his track, with a few miserable-looking dogs, but which from their snapping bark appeared to have some idea of scent. After wishing them good luck, we passed on and came suddenly on a party of thirty men all armed to the teeth with spears, blowpipes and creeses and coats made of rhinoceros hide. On enquiring I was informed they were going to have a conference with another tribe. At first we were both rather reserved, but, as our road appeared the same as theirs, we soon got communicative, and at night we all camped down together, Men were put on at once, and before half-an-hour a house was made out of bamboo and coiled cardamom leaves large enough for us all, now numbering close on 50. The flooring was also made from split bamboo, resembling cane matting, and which method I had not before seen. I secured one end of the house and made

myself comfortable, but had an incessant crowd round about me. My first thought was to change my wet clothes for dry, and the usual curiosity existed to see if I was white *all over*. Having finished my toilet I was glad to get my dinner, as we do not stop in the middle of the day for a meal when on the march. I noticed some of the guides explaining the whole of this business and looking very wise over it. I thought the fact of my having dinner might induce them to go and do likewise, but not so. First my watch, India-rubber sheet, rug, and, last but not least, my revolver, were all objects of great curiosity to them, and the last thing I remember before going off to sleep was a lively discussion among the guides as to what my aneroid was. Prior to going to sleep I had a small talk with them about growing rice, and tried to explain to them the system of irrigation which they would find more suitable than their present hill paddy which necessitates their constantly changing their land and home for other localities. They appeared much interested, and stated if they were once shewn it would be quite sufficient. Next morning I obtained two of the band to shew us the road to the plain of Tambunan, but could not get them to come farther than the outskirts, as they are not on friendly terms with the inhabitants. We, however, came across a native belonging to the place who shewed us the rest of the way and who informed me that Mr. Witti, the exploring officer, and his party, were resting there, having been visiting the country to the south. I was much struck with this fine plain after having seen nothing but jungle and scrub for the last few days. It reminded me much of what Kandy must have been in its early days, and I hope before long to see it a thriving little town. Mr. Witti introduced me to the chief, who provided my men and myself with accommodation, and in the evening we witnessed a ceremony of friendship, which consisted of a stone being put up and a goat slaughtered in commemoration of our being the first Europeans who had ever visited them and to many the first white man they had seen. The men and children, notwithstanding there is a nice river close by, were very dirty, but the women appeared very neat. As is the custom in Borneo, they do all the work and the men the fighting and the drinking. Their dress consisted of a short petticoat, generally made from the cotton they grow themselves, with coils of wire round their hips, which looks rather nice. In the case of young girls who have had no child, they wear a strip of cloth across their breasts. Their agricultural duties appear to agree with them, and one could not wish to see a more healthy lot. On first sight the village appears from the houses to be thickly populated, but on inspection many of these houses have nothing but one big cask in them made from the bark of the sago tree, in which their paddy is stored. The place swarmed with pigs and dogs, who appear to do all the scavenging. I decided during the day to alter my previously arranged plan and join Mr. Witti and his party; so I handed over to him all my trade goods, consisting of beads, cloth and looking-glasses, and sent my men back to Pappar. Mr. Witti I should mention is the exploring officer of the Company and has seen more of the inland portions of North Borneo than any other officer. His reports and survey of the country he has been through are very interesting, and one can only understand properly the difficulties and hardships experienced by him by taking a small journey one's self. On the following day we walked over to another village to attend a feast, which was held in a large house. Along the usual verandah there were about 30 pigs, all waiting to be slaughtered. This is performed in rather a strange manner: a small incision being made in the chest, and then a stick inserted which destroys the lungs, and the pigs bleed inwardly. We partook of some hard-boiled eggs and rice toddy and then returned. There appear to be several little villages on this plain, and strange to say many of them are on very bad terms with each other. Only parts of it appear to be cultivated: those that are very flat are irrigated, but no signs of terracing are seen; neither do the people appear to have any tools. A fine mountain range I see to the N. E. is, I am informed, called Madii: this I hope to explore in a day or so. Next morning we made our start, our guides as usual being late; so we went on and told them to follow. Our track led us over small hills, which shewed signs of previous cultivation. Towards the end of the day I obtained a good view of the Todus Madii range, the highest point being, I should think, about 7,000 feet. It was a pretty piece of jungle, reminding me very much of what the Pundaluoya Valley must have been before it was felled for coffee and cinchona. In one of the gardens we passed through I noticed tobacco growing remarkably well. There appear to be two kinds grown: one having the large cabbage leaf like that grown in Ceylon, and other the long narrow leaf closely resembling that grown in Sumatra. On enquiry the natives told me they prefer that of the former. I was shewn some of the tobacco which was already cut up and ready for smoking and which looked and smelt very nice. It does not appear to undergo any fermenting in the curing. The leaves are picked when ripe, and cut up in bundles very fine, and put out to dry for a few days, and to look at it one would think it was European. No attempt has ever been made as yet to make cigars. We came across a house towards evening and put up in it for the night, and made ourselves quite at home. On the following morning I found it rather cold, but then Dusun houses are generally rather airy. Before continuing our journey we were pressed to witness the usual ceremony of friendship, a chicken instead of a goat being decapitated. Our journey today was rather difficult, one moment up a hill, and then crossing a river below, and so on, but we came across a solitary house in the evening, and put up for the night. The practice of displaying wisps of straw on the roofs of the house was pointed out to me, each wisp denoting a head, but on entering I could see no signs of these skulls. As our journey for the next few days will take us through country totally uninhabitated, we have to stop here for a day, and bring and pound some paddy, there not being sufficient rice ready for our party. During the day neighbours came in to see and talk with us. The men and children are as usual very dirty, and covered with sores, to which Mr. Witti willingly gave his attention, the white man's medicine being of course an object of great curiosity. The women were busily engaged pounding rice for us the whole day, their task being finished when darkness came on. The usual bartering was gone through, a small quantity of beads, cloth, etc., procuring enough rice for our journey. I notice the Dusun men very seldom have hair on their face, but, if they have, are very proud of it.

There was heavy rain during the night, making walking rather difficult. From 2,900 we began to ascend, getting into the Madii range. Dusun paths, however, are not very satisfactory to me, as they generally are up ridges. The top was duly reached: from here (4,620) I was able to get a good view of the range in front of us, while away to the north old Kinabalu was to be seen standing boldly out. The jungle round me was fine, and the soil good. From here we again descended and crossed a small river, and then made a leaf hut for the night. It rained heavily, but then we must expect that at this time of the year. We made the usual early start and partook of our morning meal of rice and salt at a

stream we came to, the water of which we both greatly appreciated. Our journey today resembled closely that of the day before, but, owing to the rain, we halted early in a small cave on the banks of a stream ; which came in very useful. This kind of weather is very annoying to Mr. Witti, who has to attend to the survey department of our trip. Our guide whose teeth were chattering informed us this was the last water we should get till we got to the other side of the mountain, and strongly advised us to stop, and so we did, but we cannot believe these men, as we have already discovered from experience. Owing to the cold we neither of us got much sleep, the thermometer being 55 in the morning. We were both glad to be on the move, and soon found ourselves on a small native track which was to take us over the range. At 6,280 we obtained a very good view of the land around us. The jungle was fine, and the soil excellent. One peak to the S. S. W. must be over 7,000 feet. From here our journey was rather difficult, being through a region of moss, orchids, etc., but at last we reached the pass at the top, which we found to be 7,000 feet. Our reception, however, here was not very warm. In the afternoon rain had already commenced and a heavy mist spoiled all chance of a view. We, however, waited an hour, hoping it would stop, but it became if anything worse ; so the order to proceed was given, but not before we had named the pass after Sir Rutherford Alcock and celebrated the event with a drink from our flask, which for the first time we found we required badly. Our men appeared rather glad to descend from this cold spot, and I was glad to find that our path on this side led down a valley and not like on the other side a ridge. The soil continued good, and the timber excellent ; fine straight stems, and no signs of wind or dampness. We descended to 5,000 feet, and then made a house for the night. The thermometer next morning quoted 60°. We continued our descent, and at 2,000 feet came to where two rivers met, the course of which we followed, and soon came upon signs of cultivation, eventually a miserable little house in which we put up. The occupant appeared to grow cassava principally, which composed our dinner, the taste reminding me very much of English chesnuts. Some toddy also made from it was very good and better than that I tasted previously made from rice. On the following day we found we had to retrace our steps a little, and follow the course of the river we had left the day before. Coming to a plain I obtained a view of this side of the mountain. I should think the highest average height would be about 5,000 feet. It will be a very pretty sight when this range on both sides is covered with plantations of tea, cinchona, cardamoms, and coffee, as I have no doubt it will be some day. Arrived at a small village we halted and had some hard-boiled eggs. The occupants of the house we stopped at had also some meat in jars they were anxious to sell our men. I fortunately left the house before a jar was opened, but Mr. Witti, who came out of the door like a ball out of a cannon, appeared to have lingered a little too long.

We were soon on our travels again and reached the village we wanted to stop at about 3 in the afternoon ; found out the chief's house and made ourselves comfortable. The male population, however, appeared all absent but came in during the evening. I noticed skulls here for the first time, but they did not appear good samples. I was amused to see a leaf out of a novel bartered for a fowl, the natives looking upon it as a sort of charm ; the pieces of broken glass and an empty biscuit tin which one of our men had, also procured two of the feathery tribe. Before night the usual ceremony of friendship was gone through. On the following morning the whole place was enveloped in mist, but cleared soon after we were on our road. I noticed our party is daily increasing, as at every village we come to these inhabitants want to come as guides ; of course receiving a small remuneration in the shape of a piece of cloth Our journey for the next few days had nothing of particular interest except the rain and the leeches which were annoying, especially as we had to make rather long journeys. We were today able to see the plain of Limbawan, which we are making for and which appears quite as big as Tambunan. It was dark when we reached a fair-sized house, and several of our men had tailed behind, but turned up shortly afterwards. We found, however, we could get very little rice and nothing else ; so we decided to push on next morning for a small village a little out of our way and get our morning meal then. Our guide informed us it was quite close. On asking him what quite close meant, he said the time occupied in reaching the village would be the same as that required to smoke two cigarettes, but the cigarettes this man is accustomed to smoke must be rather queer ones, as we did not reach the place till nearly twelve o'clock, but luckily we were able to get rice, coconuts and plantains, to which we all did ample justice. After we had finished our meal, we pushed on for Limbawan, crossing a rather difficult river, but which we have by this time got accustomed to. This plain like Tambunan is exceedingly pretty, but it was a feeling of regret to me that this fine green extent was not paddy instead of being covered with the lalang and other coarse grasses. We walked some distance before we reached the village. Mr. Witti, who had stopped here once before, painted it in rather dark colours, but I must say he did not at all exaggerate the picture, the people and their dwelling-places being filthy. It is here the custom to bury the dead in jars, which they place under their houses and heap up a small mound of earth round it, but piggy and his friends soon knock this down—in fact, most of the jars I saw had the earth at the top removed. In entering the village we came across a party of women gaily dressed. On enquiry I was informed that this was their drinking costume, and that they were on their way to one of these festivals. The chief placed a house at our disposal and a young buffalo was purchased, which an hour afterwards we were all busily eating. It had been understood between Mr. Witti and myself that from here we were to strike across to Sebookoo, our south-eastern boundary, the country having never been explored, but from letters we found awaiting us we were requested not to do so, as the boundary question with the Dutch Government was now being settled, and our travelling through the country might lead to some misunderstanding. It was very disappointing, but we were both glad the letter reached us in time, as we should have been sorry if our trip had raised any ill-feeling. Mr. Witti continues his survey, but the country he is going to visit does not require attention so much as other localities : so I return to Kimanis, our present south-western boundary. On the following morning Mr. Witti and his remaining followers saw us some way on our road and we then parted, both sorry to leave each other but anticipating another pleasant trip together before long.

My party consist of men who have the pluck but not the stamina to follow their leader. From 900 feet we ascended to a village at 2,400 and put up init for the night, the country we had passed through being principally Dusun gardens which contained the usual sugar-cane, Indian corn, tobacco and rice. On the following morning we continued our journey, having procured a guide who was to take us to a village at which we would arrive at 4 o'clock, but this guide turned out a regular scamp. We reached his village at 10 o'clock, and of course I declined to stop, not-

withstanding he informed me we should not get water again. We arrived at the top at last, 4,700, and then began our descent on the other side, having made a further arrangement with our guide to go on till evening with us, but to serve his own convenience he took us down the wrong road, as there was a ready made Dusun hut close by; but I declined to stop it being only 2 o'clock, the usual alarm about no water, no house, &c., &c., having no effect on me. From the untrodden appearance of the track, I was certain this was not the right path, although he firmly stated it was. About 5 o'clock we came to a ravine, and I decided to halt here, but my guide informed me if I went on a little farther I should find a leaf hut. This was the only bit of truth that came out of him. We found the usual little bags of rice, tobacco, etc., hung up, belonging to same Dusun who was either away trading at Kimanis or hunting gutta. It is an understood thing amongst them not to touch what does not belong to one. I was told if one of these little bags was stolen there would be a tremendous hue and cry all over the country. I was very lucky to be in a watertight hut, as it rained heavily all night and consequently the rivers were much swollen in the morning, making wading very difficult. The guide expressed a wish to return, but I declined to allow him, as I told him he had brought us into a path we were all ignorant of and where we had no chance of coming across any travellers, as we would have had if we had gone down the proper ridge. However I came into a track I had travelled before; so I allowed him to return. Soon after we came into the green pastures above Kimanis and then to the river. Here we borrowed a boat and floated down with the current to the Residency, Mr. Dalrymple, the officer in charge, kindly attending to our wants. On the following day I went round, by boat to Pappar, which brought a very pleasant and useful trip of a little over 3 weeks to an end, which, thanks to Providence, was marred by no accident. Two of my party were men from Tambunan and had never seen the sea, though their village is only four or five journeys from here. What strikes one inland is the independent manner of living among the natives. They appear to have as much rice as they want, they grow their own tobacco, also cotton for making their clothes, and out of rice they manufacture their toddy. Everywhere we went they appeared happy and contented, and we and our party were everywhere most heartily welcomed, though the first white men many of them had seen. I saw no sign of persecution or slavery: in fact slavery out here is very different to what people imagine it at home. The few slaves I have seen have invariably been fine men who to all appearance are one of the family; they are generally married and have children who appear quite as well cared for as their parents.

Selam, July 11th.—I intended closing this at Kuddat, but I found so much correspondence awaiting me that I was unable to do so. Mr. Collinson I found very busy surveying this rising little town and superintending the erection of several buildings. I return there in a few days to see the country around which is said to be first-class and easily got at.

The experimental garden here is progressing slowly. I am anxiously awaiting the result of Sir Walter Medhurst's mission to China, and have no doubt in the course of a month or so I shall be able to announce that suitable labour is both abundant and cheap.

Selam is already a small Ceylon colony, Messrs. Lempriere and Callaghan both being old Ceylon planters. The former fills his position as Assistant Resident with both grace and dignity, and gives us every assistance that lies in his power. I was sorry to find on my return here that Bagoos, one of the conductors I brought with me from Ceylon, had been accidentally killed from a tree being felled on him. Everything that could be done for him was done, but he succumbed to concussion of the brain a few hours afterwards.—Yours truly, L. B. VON DONOP.

LIBERIAN COFFEE IN JAMAICA: INFORMATION ABOUT PULPERS ASKED FOR.

Botanical Department, Gordon Town, Jamaica, 22nd June.

Sir,—As some of our Liberian coffee trees on private plantations are coming into bearing it would be interesting to learn for the information of planters in the West Indies whether you have at work in Ceylon a "pulper" successfully adapted for cleaning the Liberian coffee bears.

Naturally the difficulty with the Liberian coffee planter, when his first crop is produced, is the removal of the somewhat hard fibrous covering of the beans, and to those accustomed to the treatment of the ordinary or Arabian coffee the subject at first sight is somewhat discouraging.

I have no doubt, however, that the problem has, ere this, been solved by Ceylon planters, and you would confer a great benefit on planters of the new coffee here if you were to publish the results achieved in Ceylon in this connection. It would also be interesting to learn whether, as compared with Arabian coffee, the pulping and subsequent treatment of the Liberian coffee is more tedious or expensive?

I have noticed with pleasure the good prices obtained for Ceylon-grown Liberian coffee at New York, which appears to be the best market for this kind; and Ceylon planters are to be congratulated on having taken the lead in placing this coffee in the market as an article of commerce. I must not, at the same time, forget, to congratulate you personally upon the establishment and extension of Liberian coffee, in Ceylon, for the *Ceylon Observer* undoubtedly did great service in bringing Liberian coffee into notice, and its columns were for a long time the chief repertory of all the practical knowledge we had on the subject.

We cannot hope in the West Indies to compete with Ceylon in the growth of Liberian coffee, for our lowlands are limited in extent and for the most part taken up by sugarcane; but, I believe, that before many years have elapsed we shall export an appreciable quantity of this coffee. I have just seen a good patch of Liberian coffee growing freely and well, at almost sea-level and on land exhausted by about 180 years of sugarcane cultivation. The yield was estimated at the rate of about 10 cwt. per acre with trees 3½ years old at 9 ft. apart. The trees established in Jamaica had not up to a late date afforded all the seeds we required, and in order to meet the large demand for plants we had to procure seeds from the trees so successfully established at Dominica by the late Dr. Imray. This year we are having large crops everywhere, so there is practically now no limit to the cultivation.

Our crop of Blue Mountain coffee is the best for several years and is only to be approached by that of 1879, and although small compared with the total exports of Jamaica coffee it is of considerable value. The total crop of this fine coffee for 1882 will probably reach some 12,000 cwt. which is shipped chiefly to the Liverpool market Although the prices of coffee generally are very low just now, Blue Mountain coffee is apparently unaffected, for already prices ranging from 130s to 135s and 140s per cwt. have been obtained by several properties. As this coffee is wholly cured on the estate and only leaves just before shipment, the expenses of pulping, curing &c. are necessarily higher than they are in Ceylon. In spite of this, however, the cultivation must be highly re-

munerative, and it is a matter of regret that it is not more widely extended.—Believe me, very faithfully yours, D. MORRIS.

[There can be no question that the unequal size, often, of the Liberian beans renders the process of pulping difficult. Messrs. W. Forbes Laurie, W. Leechman and others can afford the information desiderated by Mr. Morris, and we have no doubt that the leading pulper manufacturers of the world, Messrs. John Walker & Co., will be able to meet and overcome the difficulties.—Ed]

THE CULTIVATION OF CINCHONA: SCHROTTKY'S EXPERIMENTS.

To the Editor of the "Chemist and Druggist."

Sir,—Referring to Dr. Cochran's letter to the *Analyst*, inserted in your last issue (p 249), the following information may be of some interest:—

I have just completed the analysis of two sets of succirubras, each set consisting of 100 trees—one set being treated according to Mr. Schrottky's method, the other not:—

	Before	After
Quinine	1·00	1·04
Cinchouidin	2·41	2·13
Cinchonin	1·37	1·39
Quinidin	0·02	0·11
Amorphous	0·60	0·60
Total	5·40	5·27

Practically the two sets are identical, and are remarkably accordant for two sets of similar trees. Possibly Mr. Cochran did not have the opportunity of analysing such a large quantity of trees; and experience has shown that two succirubras, identical as regards age, appearance, growth, &c., differ very widely from one another in the percentage of quinine, &c.

At the same time it is possible that this particular set of trees were not under suitable or favourable conditions for enjoying the benefit of Mr. Schrottky's nostrums, and that later on we shall find that he is right in his experiments.

The following analysis of some "hybrids," &c., forwarded at the same time from Ceylon, may also be of interest:—

No. 1.—Six-year-old tree, Pata de Galinazo type.

No. 2.—Dark shining leaf, succirubra shape, but not wrinkled.

No. 2B.—Hybrid, succirubra type.

No. 3.—Hybrid, pendant-branched, condaminea type of leaf, rough bark. Seven years old.

No. 3B.—Hybrid, a good deal of officinalis type.

No. 6B.—Hybrids Nos. 1, 2, 3, and 4. Six to seven years old.

	No. 1	No. 2	No. 2B	No. 3	No. 3B	No. 6B 1	No. 6B 2	No. 6B 3	No. 6B 4
Quinine ...	1·15	1·21	0·84	1·65	2·68	3·11	1·79	2·79	3·61
Cinchouidin ...	4·06	1·11	1·05	2·62	3·81	1·92	1·89	3·88	4·78
Cinchonin ...	0·84	2·41	2·24	0·30	0·37	0·73	2·15	1·03	0·41
Quinidin ...	0·15	0·41	trace	0·12	0·07	0·10	0·21	trace	0·11
Amorphous ...	0·42	1·07	0·86	0·51	0·19	0·18	0·98	0·65	0·19
Total ...	7·62	6·21	4·99	5·20	6·12	6·04	7·02	8·35	9·39

I am, sir, yours faithfully,

Stratford, E. JOHN HODGKINS.

Indo-China Tea Association.—Some short time since we noticed the opening of the first four retail establishments of this Company for sale of tea to the public. The Association now announces that it is prepared to undertake the consignment and sale upon the home market of teas direct from the plantations, and to enter into special arrangements with planters whose teas are suited to the requirements of their establishments.—*Overland Mail.*

To Remove Lime from the Eye.—Lave the organ with *diluted* vinegar.—*Indian World.*

The Sale of Valuable Seeds from South America by Mr. C. E. H. Symons, of Colombo, was, we are sorry to learn, not a success owing to the cinchona calisaya Morada seed having come to hand in the husk instead of "clean," as was expected. It was deemed advisable to have the seed cleaned and it will be offered for sale again next Saturday. The maize seed sold at R5 per ounce and some of the coca at the same rate. There were no bids for the other seeds. The Java ledger seed sold at an average of 80 rupees per ounce.

The Liberian Coffee Pulpers made by Messrs. J. Walker & Co., Mr. Morris will be glad to know, it is confidently predicted, will do for Liberian what their other machines have so successfully done for Arabian coffee. The following are a few advantages secured by the Liberian coffee pulpers:—1st.—They are simple and all the working parts are easily got at. 2nd.—They are substantial; are not likely to get out of order, and can be driven either by hand or by power. 3rd.—They do their work thoroughly and without damage to good coffee. These pulpers are made in sizes to suit requirements from £18 to £130 in price, and pulping from 10 to 80 bushels per hour.

Enemies of Tea in Japan.—Towards the latter end of last May destructive green worms made their appearance in the tea plantations at Uji. They turned into butterflies and spread rapidly by the middle of June. Mr. Kitagaki, the governor, and some officials of the industrial Bureau, visited the plantations, and by their advice and example induced the people to engage in a general slaughter of the obnoxious insects. At length it was thought they were all killed, and then to make sure of extirpating them the governor offered a reward of 4 rin for every worm or butterfly produced at the Fucho. The whole neighbourhood then turned out, and engaged in the chase with such vigour and success that in a short time over 120,000 of these insects were brought in, and a bill of over 600 yen incurred.—*Hiogo News translation.*

Jute Preparations.—We believe that it is the intention of the Bengal Government to procure at as early a date as possible one of Messrs. Dennis and Angell's machines, a short description of which we reproduced in our columns on the 25th July. Should the machine be equal to all that is claimed for it, it will certainly effect a considerable change in jute manufacture and fibre manufacture generally as at present practised. The Minister at Washington has as yet been unable to procure Dennis and Angell's fibre preparing machine, as it is still imperfect in many details and consequently the inventors are not prepared to offer their machines for sale. As soon, however, as the machines are in the market, one will be procured, as we have said, by the Government.—Calcutta *Englishman.*

Gums and Resins—In order to ascertain the free commercial value of the gums and resins to be obtained in the forests of this Presidency, a collection, made by the officers of the Forest Department, was forwarded by the officers of the Local Government to Her Majesty's Secretary of State for India for examination and report, by competent authorities in London. On arrival in England, the samples were handed over to Messrs. Burgoyne, Burbridge, Cyriax and Ferries, of Coleman Street, London, and from their report it appears that the gums of Acacia leucophlea, (Salem); Ailanthus malabarica, Bassia latifolia, Bombax malabarica, (Wynaad); Hardwickia binata, (Salem); Moringa pterygosperma, (Trichinopoly); Buchanania latifolia, (Coldapah); and some others, were found to be of very low quality and not worth importing.—*Madras Mail.*

CITRON-ORANGES.—Large quantities of citron-orangee have been received from Jaffa, and its neighbourhood. They are produced from orange-sets grafted on citron-stocks. They are much larger than oranges, and sell for 10 to 20 leptas each. The oil obtained from the peel by distillation or by the Sicilian method of expression differs from both orange and citron oil. —*Chemist and Druggist*.

PLANTING IN SARAWAK.—Mr. Loyalty Peake writes to us by this mail :—" My cinchona nurseries are now doing very well and the plants looking very strong and healthy. I have some succirubra about 10 months old from date of sowing seed, about 3 feet high, and very vigorous. I was fortunate enough to obtain ½ lb. of Ledger seed from Mr. Gammie and a small quantity pubescens. I have also the promise of some Java Ledger from the Dutch consul in Singapore. I am also trying tea, Liberian coffee, cocoa and rubber : present appearancee are in favour of them all."

HYERIDS.—It has long been matter of dispute with eome as to whether in-and-in breeding is *per se* inimical to health. Notwithstanding that it has been shown, times out of number, that all the greatest improvements in the domestic animals have been brought about by closely in-breeding, many fail to be convinced that it does not result in degeneration. Mons. V. La Perre De Roo, of the Société d' Acclimatation, France, has published a work on " consanguinity." In it he states that at one time he shared the common opinion, which led him to make various inquiries as well as to experimeut upon animals. The net result of these observations and inquiries—practised at the institutions of Parie, Lyons, Bordeaux, Rouen, Antwerp, Liège, Berlin, Munich, Milan, &c., and also at the chief sheep depôts of France, and of the experiments made and continued for twenty years on all sorts of animals—is that the ill effects attributed to consanguinity are purely imaginative. So convinced is Mons. De Roo of the absence of any evil effects from in-breeding that he says, " the question of consanguinity does not deserve to be considered by science."—*Queenslander*. [This is contrary to Darwin's doctrine that an occasional cross, even with an inferior variety, leads to good results.—ED.]

INDIAN TEA.—Several small invoices of new season's tea have been placed on the market, representing some of the principal districts, and in every instance the quality appear much below the average of the first imports of previous years, thus confirming the early advices. The recent news of the crop has, however, been more encouraging, and the latter shipments will probably brig stronger and better teas. It will be more than ever necessary this season for the Planters to produce Teas possessing the above characteristics, and even in some degree to sacrifice weight to quality. Indeed, it has long been a question whether the incessaut pickings in India are not likely to bring about in time blights and other plant diseases, which will seriously compromise the industry. The Chinese do not pick the leaves nearly so often as is done in India. It is true that their climate, at any rate in the northern districts, is not so hot and moist as in Assam, so that the flushes are probably not so frequent. On the other hand, the Chinese variety of the plant has not nearly so strong a growth as the plant indigenous to India, and it is obvious that incessant pruning and picking is more likely to do harm to what, if left alone, would grow into a tree, than to a plant that would not become more than a large bush. If iucessant pickings are kept up, it is a matter of consideration whether it would not be desirable to let the plants lie fallow at intervals to recover themselves, and in any case, the complaints of various blights already heard in India are of serious potent.—*Produce Markets' Review*.

ANTIMONY.—Our supply of antimony has hitherto been brought from Great Britain and the island of Borneo. But mines of it have been found in the southern part of Utah, whence ten tons of ore, yielding 60 to 65 per cent of antimony have lately been received at Baltimore.—*Oil and Drug News*.

A MEMORANDUM FOR EVERY PLANTER'S NOTE-BOOK. —The following may be accepted as the dates on which tea cultivation commenced in the different districts :—Assam 1835, Kumaon 1850, Cachar 1855, Dehra Doon 1855, Sylhet 1857, Kangra 1858, Darjeeling 1860, Terai 1860, Chittagong 1860, Neilgherries 1862, Chota Nagpore 1872, Dooars 1875. These dates are from a London contemporary, and we believe are generally correct.—*Indigo Planter's Gazette*.

TEA.—In the following advice to Managers of tea gardens is given in Messrs. Moran & Co.'s last circular :— " The manufacturing season is now about half through, and we would again warm all concerned in the industry against overplucking. Production eo far is generally much ahead of what wae expected. This has bees brought about in a great measure by the leaf having, chiefly in Cachar, come out faster than usual owing to favorable growing weather, but, unfortunately, in some cases, too fast to allow of its being plucked sufficiently quickly. When this is the case, of course a large quantity of leaf accumulates, and cannot generally be worked off fast enough to make good tea, and consequent on this is the falling off of the quality which has in many cases been noticed."—*Pioneer*.

WHITE ANTS.—If X. will try kerosine oil, I think he will not be disappointed. It kills all black ante it falls on almost directly. Whenever black ants appear, I stuff their holes up with cotton or cloth well wetted with kerosine oil, and pour some round the holes. They won't go near it. It is equally good for white ants. They will not touch anything rubbed over with it; nor will they appear again (at least for a long time) where it has been put down. If the ants (black or white) appear high up on a wall, squirt kerosine oil into the holes they have made. I should think it might be tried on trees with great advantage to save them from white ants. The wood-work of doors and windows, and innumerable other things, can be preserved by being rubbed over with a cloth wetted with kerosine oil, I am quite surprized how few people know of this simple and cheap remedy for getting rid of ants of all sorts. I don't see why it should not answer for other insects, but have not as yet tried it. —B.—*Pioneer*.

JAPAN TEA TRADE.—Conflicting rumoure as to the actual condition of the American tea-markets generally continue current; some evidently taking a pessimist view of the position, whilst others show, that although no very brilliant results can be expected, affairs are not really so bad as some would make out. We believe that when the present feeling of alarm amongst buyers in New York—caused by the unprecedentedly large shipments from this,—has subsided, it will, as a rule, be found that the tea crop of the present season has been—as regards quality—the best that we have had for several years. The only fault about it is the price, and for that the Japanese are not to be blamed. We hear that, thus far, the results of the campaign have been very satisfactory to native producers, although they still complain of the high cost of labour resulting from the present enhanced prices of most of the necessaries of life. We trust, that for the balance of the season, the producers will not fall into the grievous error of bringing into this market an inferior article, with the view of saving the expense. It would be far better for them to sacrifice some, if not all their profit, than to adopt any course which may again endanger the popularity of Japan Teas in the States—a popularity which they now seem to have a good chance of regaining.—*Japan Herald*.

COFFEE LEAF DISEASE.

What may be done to check coffee leaf disease is thus mentioned by Mr. E. M. Holmes, in a letter to the *Planters' Gazette*:—

1st.—To select for fresh plantations at a proper elevation the side of a hill which is leeward of the wind which prevails at the time the fungus usually appears, so that the shelter of the hill may prevent the spores being readily carried to the trees, and the trees themselves from being liable to such sudden changes of temperature as if exposed to the direct action of the wind. Where it is not possible to select such a situation, some shelter might, at all events, be made by growing a barrier of taller trees between different plantations, more especially on the side on which the spores are likely to be brought by the prevalent wind, trees of leafy habit and not belonging to the natural order *Cinchonaceæ* being selected.

2nd.—It is very important also to ascertain as far as possible the freedom of the seed sown from the fungus. It has recently been observed in this country that the hollyhock blight (*Puccinia malvacearum*), which in a remarkably short space of time spread over the whole of Great Britain, although quite unknown here before, attacks the seeds of the common mallow, and thus gives rise to the same fungus in the seedling plants. (*Gardeners' Chronicle*, July 15th, p. 87.) It is quite possible that the coffee fungus may be propagated in the same way.

3rd.—Probably it might be a wise plan to destroy trees whose vitality seems very low. Although cases are on record in which a tree stripped of its leaves by the fungus one season may yield a very heavy crop the next, yet in such case the tree has probably made vigorous growth previously, and a cessation of a drain upon its resources by the non-production of fruit one year enables it to produce more the next. It cannot be hoped that the fungus will ever be exterminated—it is sure always to be latent on the wild coffee and *Canthium*, as well as in weakly trees, awaiting only favourable conditions to enable it to spread. Weakly trees will help to do this by affording suitable conditions for the development of the fungus, and serving as a sort of centre for its distribution, and their destruction by fire might lessen the evil.

SUGAR IN INDIA.

The map of cane areas in the North-West Provinces and Oude, prepared by Mr. Buck, C. S., Director of Agriculture and Commerce, gives the percentage of the area under cane in the various districts as averaging from one to eight per cent. The census returns of 1871-2 give the area of the sub-Himalayan portion of the North-West Provinces as 69,903 square miles, and of Oude as 23,992 square miles, or together, a total of 93,895 square miles. The report of the Assistant Director of Agriculture and Commerce states (see North-West Provinces Circular, No. 8, of 7th July, 1880) the area under cane in the North-West Provinces and Oude to be 1,067,000 acres—1,668 square miles, or about 1·75 per cent of the whole area. This includes an increase since 1876-7 of 160,000 acres, or 250 square miles which is only 0·26 per cent of the total area.

We estimate the maximum average produce of raw sugar (goor or jaggery) to be about 30 cwt. per acre, which makes the total yearly production over the above area to 32,000,000 cwt., which at 7s. 3½d per cwt. equals £11,666,000. By being doubled, the area under cane would be only 3½ per cent of the total area, and at the rate of increase between 1877 to 1880, above alluded to, this may be done in 25 years.

Assuming the out-turn from this area to be at the rate of 30 cwt. of "goor" per acre, and the value at 7s 3½d. per cwt., we have 42 million cwt. of raw sugar produced annually, worth £15,312,000; here also, if the area under cane were doubled, it would be only 2·76 per cent of the total area. The Punjab, Madras, Bombay, Burma, and the native States produce sugar in quantities of which it is difficult to get reliable figures, but suppose it is half as much as that of the Gangetic valley, the total would be 111 million cwt., or 51 lb. per head of the population.

The exports are comparatively small, only 368,546 cwt. in 1879, while the imports were 923,381 cwt. It thus appears that India is producing sugar for home consumption only, and at the rate of 51 lb. per head of population. (This does not include the produce of the date palm, which is considerable in some parts of India.) To those acquainted with the habits of the agricultural and labouring classes of India, this will appear more than a liberal allowance for consumption. (In 1880, the consumption per head of the population of the United Kingdom was about 63½ lb.) It is evident the production could be easily doubled, without making an undue and disproportionate demand on the supply of labour and land. Any increase in the area under cane, will tend to reduce the present low prices, if it be greater than a proportionate increase of the population. Profitable extension, then, is only possible when the cultivation of the cane, and manufacture of the raw sugar, has been so far improved as to bear export by sea, or long journeys by land, exposed to changes of weather and temperature.

The "Colonial Statistical Abstract" for 1879 gives the total production of sugar by Jamaica, Barbadoes, Trinidad, British Guiana, and Mauritius, as 6,870,725 cwts., valued at £6,967,128, being an average of 20s. 3½d per cwt.

It may be here mentioned that there is a large bi-weekly bazaar or market at our chief village, Jugdespore, and a register of prices is kept up at the zamindary office there. Taking an average of five years (the "goor," or "jaggery," being of the improved quality produced by the Beheea cane mill), the value is only about 7s. 3½d. per cwt., or a little more than one-third in value, as compared with colonial sugars. The total Indian production, 111 million cwt., if of equal quality to the sugars produced in the West Indies and Mauritius, would be worth 126 millions sterling, but it appears the Indian cultivators get only about 40½ millions for it. It is not to be expected that the necessarily domestic nature of the sugar industry of India can ever be improved to equal in quality of produce, the careful scientific manufacture of the large sugar estates in the colonies above referred to, with their costly machinery and all recent improvements. The difference is 85½ millions, and it may reasonably be hoped to recover one-fourth of this, which would amount to an additional 22½ millions sterling—a vast advantage to India, especially were this sum the equivalent of sugar exported. There seems to be no reason in soil, climate, time, or value, and supply of labour why this advantage should not be recovered. The first necessity is a careful "garden" cultivation of the sugar-cane plant in harmony with its nature and habits, instead of the present rude field cultivation; secondly, improved means of extracting the cane juice; thirdly, the proper treatment of the juice after extraction, by cleansing and fumigation of receiving vessels, straining and removal of foreign matter, defecation and evaporation of the watery portion of the juice at the lowest possible temperature, all of which essentials are obtainable by means within the reach of the people. These remedies are within the means of the smallest cultivator, but but he is only an atom in the huge mass of the Indian ryots. Were he to step out of the rut to produce a better article, no one would give him a corresponding price for it.—*Journal of the Society of Arts.*

GAMBIER AND GUMS FROM THE STRAITS SETTLEMENTS.

A staple article of export from the Straits Settlements is gambier (terra japonica), derived from the gambier vine, which latter is most extensively planted by Chinese exclusively in the province of Jahore and other provinces on the Malay peninsula, and in Sarawak, Borneo, as well as on several islands in Netherlands India, south and near Singapore. Our Consul at Singapore, Adolph J. Studer, writes as follows regarding it:—

This vine grows so luxuriantly and bushy that it will exhaust the fertility of the soil in a short time. After a few crops (clipping of the shoots and tendrils) the land is abandoned, and proves worthless for several years. Notwithstanding this, the demand for gambier is constantly increasing, and with it, of course, the cultivation of the vine. Gambier planters are constantly on the move for new lands, which they clear and make ready for the time when the fertility of the last plantation is exhausted. They rarely fertilize, because wild jungle

land is as plenty as the wild tracts of prairie in our west. It will not pay Europeans, with their usual mode of planting in the east, to engage in planting gambier at the present prices, and Chinamen only can exist by it. Other natives, Hindoos and Malays, could also exist by it if they were possessed of the industry and stamina for making money as the Celestials are. Rich Chinese capitalists, known as "Towkays," upon the arrivals of shiploads of poor coolies from China either hire them and make contracts with them for planting and boiling gambier, or they advance them money upon condition of obtaining a certain share of a crop, and take care that they receive the "lion's share." Those gambier-planting coolies are little better then slaves, since, as a rule, they only earn a scanty living. But it is wonderful with what tenacity they stick to their "Towkays" until they get a little better acquainted in the country, and find they can do better at something else. By dint of careful management and great industry some of the coolies that plant on shares earn a little more than a living, and invest this in such a careful manner in something or in some way, that in a few years they become small "Towkays" themselves, and pretty soon wealthy ones. There are to-day in Singapore immensely wealthy Chinese "Towkays," who were once gambier-planting coolies. The same or a similar mode is observed in tin mining.

The only marketable gambier is obtained ("cutch," or "catecu," a species of gambier, planted in British Burmah, and the coast of Tenasserim also) by boiling the clippings (shoots with leaves and tendrils) of the vines in huge boilers; the mass is strained and the extracted juice is boiled until it becomes thick; when cooled it is pressed into square blocks or "cubes." When pressed into small cubes it goes into the market under the name of "cube gambier." The latter sort commands a higher figure because it is treated with much greater care and is more free from foreign matter.

Gambier possesses "tannin" in a high degree, and is exported chiefly for tanneries in Europe and America as a very excellent substitute for bark. It is also used for dyeing, and in a purified state for medical purposes, being a great astringent. I have also been told that beer-brewers purchase it, but I have been unable to learn for what special purpose—I suppose to give beer a dark brown color; if so, while it serves to cheat, it is at least harmless if not used too freely.

When I first came here gambier was not largly exported to the United States, and rather to Europe, England principally. At that time it vacillated between $3 to $3.50 per picul, and that figure was (for the common usual sort and not "cube") not often exceeded until the latter half of 1879, when it gradually rose, owing to unprecedented demands, to $4 and over, and this without getting lower than $4 to the present time.

The exports of gambier to the United States during the last three years have amounted to $1,060,619.05. Considering this large quantity, it must be extensively used in tanning and must be regarded at home as a profitable material for that purpose.

The blocks, in which shape gambier is exported, being very heavy, the article comes very handy as "dead weight" to ships loading produce, more especially since nearly all the tin for the past five or six years (the longer the more so) is shipped in steamers to the United States. The more gambier a ship can get the sooner she will be able to complete her cargo and go to sea. It is to be regretted, however, that nearly all the tin, being the best and easiest handled "dead weight" is, nowadays, shipped by steamers, carrying nearly all tea as chief cargo. Tin comes very handy to them because it is heavy and clean, and, being cast into blocks or slabs, it can be carried easily to any part of the ship for the purpose of "trimming the ship."

GUM COPAL AND GUM DAMAR.

Gum copal and gum damar, both very important articles of export in larger quantities, steadily increasing, and in price as well, have been exported.

Gum copal is a rosin of the earth, of which there are very heavy deposits on or near the island of Ternate in the Southeastern Archipelago, and at Gorontalo or Celebes, near the Moluccas. As we all know, it is used in making varnish, and nothing here could have been a better barometer of increased manufacture and building of edifices and vessels in the United States then the increased demand for this valuable gum. The average price of gum copal, including all charges, per picul, in 1878 was about $6.90, in 1879 about $6¾, and in 1880 about $12.50. Truly a strange change; and the deposits of the gum being regarded inexhaustible, I cannot account for this enhancement in 1880, except as the result of an eager demand for immediate use, old supplies having been exhausted.

Gum damar (some call it and write "dammar" which is too strong an expression, and does not sound as the Malays pronounce it, *i. e.*, sounding like damar, if pronounced by an Italian)—unlike gum copal, which is of brown color and a rosin of the earth—is a tree-rosin of light amber color, and when prime almost white and transparent. It exists in the jungles of the Malayan Peninsula and on the island of Sumatra and other adjacent islands. That brought from Sumatra is counted the best, though I have, myself, seen it on the branches of trees in the interior of Malacca, and it had as clear and white an appearance as any I have ever seen. There are, however, various species of damar trees, each producing a different shade in the color of the gum.

The gum-trees are not at all scarce. I found them always growing on the banks of rivers and creeks, the branches overhanging and so low that the gum could be gathered easily from a boat underneath, and from the most of them no gum had apparently been gathered, the branches having large adhesions of it. The price of this gum has been on a slow, constant rise for several years back, but I could not account for it through any scarcity of it in the jungle, or a scarcity of natives to go and gather it, without any hardships, except rowing and raising the hands to gather it.

The exports to the United States of gum copal and gum damar during three years ending September 30 last amounted to about $400,000.—*Oil and Paint Review.*

THE MAKING OF TEA AND COFFEE.

Some curious fanatics in matters of taste, bent on belittling the conclusions of extreme civilization, maintain that the true and only wise method of taking tea and coffee is to drink them as do the Chinese the one and the Turk or the Egyptain the other. The Celestial, who exhausts his æsthetical powers on the appreciation of birds'-nest soup, and his gastronomic on the preparation of rats and puppies in pies, puts a pinch of tea-leaves into a tiny cup, pours on to it boiling water, and swallows it. The gustatory fanatic admires the simplicity of the operation, reflects that the Chinaman grows tea, prepares it for our use, knows every grade and quality of it, and himself drinks it—ergo, the Chinaman's way of drinking tea is the best way. The Arab, again, discovered coffee, gave it to Europe and the world, drank it first and drinks it still. He roasts it a little, pounds it to a fine powder, puts it into a little copper boiler which they call an ibric, pours some boiling water on it, boils it an instant, and serves it hot, to be drunk grounds and all. Now, the Arab, quoth our fanatic, invented the beverage, grew the berry, drank it first, and drinks it still—therefore his way of drinking it is ideal; and one contiuually hears people who have passed three months in the Levant talk with the gravity of a Turk on the supreme and sublime perfection of Turkish coffee hot from the ibric, and swallowed grounds and all. Philosophy and gastronomy are both against the fanatic; the one against the assumption that the taste of the barbarian is a proper standard, and the other against the absurd conclusion that tea and coffee, which are infusions, can be rendered more delicate to the palate by the swallowing of the woody particles from which the infusion is made simultaneously with the decoction itself. I have never drunk tea with a mandarin, but I have often taken it in the houses of China merchants habituated to the Celestial usages, and as choice in their selection of the herb as Kung himself could have been, and of all varieties—Assam, Japanese, Chinese—and at prices varying from £3 per lb. avoirdupois to 1s. 3d., yellow, green, black, overland, and sea-borne. I have also had a large range of observation in coffee, my father having been a Sybarite in that article alone of all that

came on his table, with the finest of tastes for all the growths—Mocha, Java, Brazil, Martinique, Sumatra, &c.—sampling it always, and buying a bag when he found a good article, and to me coffee is the one indispensable luxury. I never, except under necessity, lunch or dine at a London restaurant, for the simple reason that I never found one where I could get a good cup of coffee when I had finished. I have drunk it in the West and the East—Paris and Constantinople, Turkish fashion and Egyptian, French, Viennese, Manhattanese—have followed the decay of its use and its gradual disappearance, until I can no longer find a cup of genuine coffee, and properly made, out of my own house, anywhere between Constantinople or Alexandria and New York. As to tea, as the *Pall Mall Gazette* has observed, there is little chance of being deceived; any respectable merchant can give you a good tea if you do not want it too cheap; but people who in London will use tea at 3s. per lb. or less must never hope to understand the question. In England most housewives understand the mystery of making tea, but few know the advantage of the Russian samovar over all other methods of making it. The samovar is a tea-kettle which has its fire in a tube running through it, and which, with a few pieces of lighted charcoal dropped into the tupe, maintains the water at boiling point with a minimum of evaporation, and gives it at that point on the table; and as a beverage the Russian does certainly surpass all other nations in tea-making. We drink it as a stimulant, and take it strong in the morning, and too strong at night, with milk and sugar as a general thing; we finish and send the tea-things away, but to the Russian it is an all-the-evening enjoyment. The samovar stands on the table, and the tea (the delicious yellow variety generally) is put into the teapot, the boiling water run on, allowed to stand a moment, and then tea is served—mild rather than weak, and more water poured on at once—a little tea added from time to time if needed. I have often seen Russian friends drink a dozen or more cups in the evening. The quick making of the infusion is in accordance with Chinese custom, but there the parallel ends. The addition of sugar—to the Oclestial a barbarism—is now opposed by some English tea-drinkers, but the overwhelming majority of opinion is in favour of its use. It seems to me as indispensable to the development of the best appreciation of the tea as salt is to that of a beefsteak. The sugar is so neutral as an emollient that it absolutely disguises no quality of the tea, and I hold it to be a cardinal principle in gustatics that where two flavours can be so combined as to sacrifice neither an advance in art is achieved. And the same is true of coffee—the addition of sugar is a development of the beverage. But milk does not come under the same category. When people drink tea as strong as most of us do at breakfast, the intense bitter is mellified by milk, but weak tea is made insipid by it.

The Russian adds a slice of lemon—the only addition after sugar which does not deteriorate the quality of a delicate tea; but he also takes a little rum—a distinct departure from the purest standard, due probably to his generally imbibing propensity. Both rum and cognac having distinct flavours which disguise the quality of the tea, are abuses unless the tea is bad. A delicate yellow tea, with sugar and lemon, is, *me judice*, the perfection of tea-drinking if made with the samovar. A hint to economists on the long steeping of tea (for boiling is a horrible barbarism never to be dreamed of): the samovar is arranged so as to allow the teapot to stand in the chimney, keeping the tea at a point just below the boiling indefinitely; and when the tea is of an old crop the flavour will be greatly and judiciously developed by fifteen or twenty minutes standing on the samovar top. A new-crop tea does not require this treatment.

The making of coffee is a much more complicated operation. Whether made in the Eastern or Western method, the precautions and most of the difficulties are the same. The choice of the growth allows of latitude, as does the choice of a vintage. The Turks prefer the Mocha and Martinique or Java mingled. It is indispensable to roast your own coffee, of whichever growth, and wise to get the best quality of its kind. The coffee-growers follow an antiquated and barbarous method of preparation, steeping the berries in water until the pulp is decomposed and rubs off in a slimy mass, leaving the berry naked. But the fermentation always damages the flavour of the coffee, and if allowed to go too far destroys it, so that many samples of coffee apparently bright are already damaged. I do not mention ground coffees, as these are anything but coffee—chicory, barley, bread crusts, any burned grameuia, acorns, juniper corns, &c., enter in; and I was told last year at Kalamata that the whole fig crop of the Morea goes to Trieste to be burned into coffee. Coffee must be roasted slowly and evenly, kept in constant motion, till the berry will crack crisply when pressed between thumb and finger. The Egyptian stops as soon as it will break any way; but this will have a slight taste of the raw berry, which seems to me a drawback. It should crack freely, but by no means crumble. Ninety-nine per cent of the people who roast their own coffee burn it, and destroy all its best qualities. From this point Eastern and Western methods differ. The Turk has slaves in plenty, and is no sparer of their labour. He has his coffee pounded in a mortar to an impalpable powder (his imitators at Athens and elsewhere fail here), and then a spoonful for each cup is put into the ibric, the water poured on hot; it is set for a few seconds on the coals, not boiled, and is poured into the cup—if for himself without sugar, if for a Frank sweetened; but I have always suspected that practices connected with Eastern politics had much to do with the exclusion of sugar, as enabling the drinker to detect certain deleterious agents sometimes introduced.

The Western coffee-maker grinds the berry, and not too fine; but the primitive ibric gives place to numerous contrivances, of which I have collected and tried many. For stupid housekeepers the best is the common French filter placed above the coffee-pot; for anyone who has mechanical ingenuity enough to use it the balance cafetière is the perfection of utensils, and should always be placed, like the samovar, on the table. But in the hands of a fool it is unsafe. Coffee with milk—*cafe au lait*—comes not under gastronomy, but dietetics. It is a bilious article of food, and better made of chicory than coffee, as the lattre is wasted when thus used.—*Planters' Gazette.*

FERTILIZERS.

BY ARTHUR G. HADDOCK, A. I. C.

By fertilizers I mean those substances which contribute to the building of the structure and the maintenance of the life of plants. In fact, I use the term in the sense of the food of the vegetable kingdom. For vegetable life requires food to support it, just as does animal life, and food also which it is capable of digesting and assimilating.

Different species of plants require different elements of nutrition; as in the animal kingdom, beasts, birds, fishes, etc., require different kinds of food.

A plant derives its support from juices and gases, absorbed through its roots and leaves. A portion of its food is contained in the air, and a portion in the soil in which it grows.

Plants are partly of an organic and partly of an inorganic structure. The organic elements, carbon, oxygen, hydrogen and nitrogen, are combined together in various manners, and with the exception of the nitrogen are chiefly derived from the atmosphere.

The inorgnic elements, together with the greater part of the nitrogen, are derived from the soil. The following substances form the chief portion of the inorganic constituents of the plant:—Phosphoric acid, lime, magnesia, iron, soda, potash, sulphuric, silicic and hydrochloric acids.

The inorganic salts form a very small proportion of the weight of the plant, as compared with the organic. The ash, for instance, of an oak tree only constitutes about 3½ per cent of its weight, but although this may seem a very small quantity it is absolutely essential that every one of those elements which go to make up this 3½ per cent of incombustible material should be supplied to the tree, or we should get a stunted growth and rapid decay.

This is the case in every instance, that the soil in which a plant grows must contain every inorganic ingredient which it requires for its sustenance or the full vigour of healthy growth will not be obtained.

Virgin soils usually contain all the elements required and in sufficient quantity to render any further addition unnecessary, and they can usually be cropped for a considerable time before any appreciable decline in the produce is noticeable. If the same plant is grown year after year, and the produce is continually being removed, the decline makes itself manifest in a shorter time, since the soil will become exhausted of one or more of the constituents necessary for the structure of that plant, which may have been present in unduly small quantity originally.

It is better, therefore, not to grow one kind of plant on the same soil continually, but to change it after the first year for another which has a different composition, and which therefore would exhaust the soil of other elements, or at all events, the same elements in different proportions. This is the reason that rotation of crops is practised. For instance, mangolds and swedes require the same compounds in almost the same proportions in several cases. They each require large amounts of sodium and potassium compounds in proportion to others, and therefore it would be unwise to cultivate them in the same soil for following years. Those salts which become deficient could certainly be added, but still unless every compound taken by the plant were replaced in proper quantity there would be exhaustion of the soil and a poor produce.

It is clear that we cannot go on indefinitely removing salts from the soil, and there consequently comes a time when no species of plant will thrive on the impoverished land, and here chemistry steps in to again make the soil fertile.

Before the time of Sir Humphrey Davy, farmers in this country had altogether worked by rule of thumb; they had used no fertilizers whatever, except perhaps the dung of the animals on the farm, and through continually robbing the land of its necessary constituents, and not replacing them, it was getting into an impoverished state. Scientific information was for a long time disregarded, and it took a great deal of time and trouble to drive into the farmers the benefits of scientific farming. Indeed, the British farmer still, in many instances, asserts his national obstinacy by refusing to consider anything of a scientific character as worthy of his serious attention. Happily, however, he is not altogether deprived of the advantages of science, since he closely watches his neighbour, who probably does believe in science, and when the results are more favourable than his own, he often copies the method of obtaining them, although he still denies the assistance of science. He thus reaps the benefit indirectly.

Scientific farming was established on a firm basis in 1840, when Liebig published his 'Agricultural Chemistry,' and for the first time publicly announced his theory that all the salts taken from the soil by crops must be returned to it in the same quantity. He put the matter, which had hitherto been in a very unsettled state, in a clear form, and traced the life and constitution of the plant to its elements in a manner as convincing as it was new. Scientific farming consequently received a great impetus, unfortunately to be again checked, as the farmers found that the increase in the crops, in many cases, did not pay for the fertilizers they had been advised to add.

Liebig considered that the inorganic salts only required replacing in the soil, and that the plant derived all its organic elements from the atmosphere. Lawes, however, showed the cause of the failure of the exclusively mineral fertilizer by proving that plants were not able to assimilate the nitrogen contained in the atmosphere, and that therefore some compound containing nitrogen must be added to the fertilizer. This admixture was found to give excellent results, and finally established agricultural chemistry as a science. It is now only exceedingly stupid farmers who scoff at scientific farming, and most of them, to a greater or less extent, avail themselves of its advantages.

There are still some who are sceptical, but I should think that the majority of these are people who have been swindled by unscrupulous dealers in fertilizers. Although farmers have been considerably educated of late, they require to be a little more so.

They have been educated, or driven, to the conclusion that they must use fertilizers, but they require educating to the further extent that before they buy they should know what the soil is short of, and then know that they are getting the fertilizer which will supply those elements which are deficient.

I am afraid that farmers, in buying a fertilizer (often the wrong one), are sometimes atrociously swindled by some manufacturers or their agents, by being supplied with rubbish not worth a tithe of what is charged for it. But such is the peculiar idiosyncrasy of the British farmer that he will rather buy his pig in a poke for, say £100, than pay about a guinea to look at it, and by so doing save perhaps £75. I mean by looking at his pig, that on buying he should have an independent analysis made by a competent chemist, and then he will know that he is getting the stuff he has paid for.

Happening to pass through a farmyard several years ago, I noticed a quantity of superphosphate of lime lying under a shed, and I asked the farmer, whom I knew, what he had paid for it. "£10 per ton," was the answer. I next asked him if he bought it on analysis: he replied in the negative. From the appearance of it I judged it to be of very inferior quality, and, for curiosity, took a sample and analysed it, with the following result:—

Water	13·86
Organic matter*	17·94
Soluble phosphate of lime	2·70
Insoluble phosphate	21·49
Gypsum	30·74
Sand	8·28
Oxide of iron, etc.	4·99
	100·00

I forwarded the result of my analysis to the farmer, and told him that I did not consider it worth more than £1 15s per. ton, and that the price charged for it was a gross imposition. He confronted the manufacturer with my analysis, and this person accepted, on the face of this, £10 for the lot, which was over 6 tons. I met the farmer about a year ago. He told me that he had bought no more stuff from this man, but was dealing with another firm. I said, "Of course you are getting this lot analysed?" He replied, "Oh, no, I did not think it worth while; they seem to be a respectable firm." The faith of that man in human nature was so touching, that I said no more, but formed my own conclusions, which were not very flattering to the individual in question.

Then suppose the farmer goes to an honest manufacturer or dealer, and gets what he orders at a fair market price. Unless he knows what the soil is short of, he is very likely wasting his money in buying an article which the land does not want. If, say, he wants to grow carrots, potassium salts will probably be deficient. It is of no use his buying phosphates, salt, etc., and manuring the land with these (if these substances are already there in sufficient quantity); as long as the deficiency in the potassium salt is not made up, so long will the soil yield poor crops of carrots. It is, therefore, of the utmost importance that the farmer should know what the crop takes from the soil, and what the soil has already in it, or at all events, leave it to someone who does know these things, and knows how to replace any deficiency.

I have known farmers who have had lime recommended to them as a manure. Lime, in its place, is certainly an excellent manure, especially on stiff, clayey, or sour ground. These farmers tried the lime, and found at first, a natural increase in the crops. But they went on repeating the same application year after year, until now they are really doing the crops harm.

For instance, a wheat straw with excess of lime in its constitution is much more brittle than the normal straw, and is therefore not able to withstand the beating and levelling effects of wind and rain. Normal and healthy wheat may be quite flattened by heavy rains, but such is the elasticity of the straw that it will gradually recover its vertical position. A limy straw on the contrary, if flattened, breaks off, and consequently dies, and rots away. As with the animal, so with the plant. If a man takes too much carbon and hydrogen, in proportion to nitrogen, in his food, he becomes inconveniently stout, and if he takes too much nitrogen, he is also inconvenienced.

Again, it is necessary that the food should be supplied

* Containing nitrogen ... ... ·10 per cent.
Equal to ammonia ... ... ·12 „

in a form in which the plant can absorb it, that is, in a soluble form, or in a form which is capable of undergoing such changes in the soil as will render it soluble. For the plant has to absorb its food through pipes in the roots, stems and leaves, which pipes are capillary, and require the substances taken up to be in solution, and not in the solid state. It is wonderful, what an influence saline solutions, and even water alone, have in time, in decomposing the most refractory substances, and bringing their valuable constituents into solution. The chief source of potash salts in the soil has, no doubt, been the primary rocks, the felspar of which has gradually got decomposed. But there are many substances containing valuable nutritive elements which are worthless as plant foods, because of their insolubility and resistance to solution in the soil.

If the ordinary farmer trusts to his own opinion as to what is the proper manure to apply to his soil, he will, in many cases, land himself in great expense and difficulty

Some (many) farmers consider that a fertilizer is worth as much as it smells, or rather, as much as it stinks, and such a one would reject such really valuable fertilizers as sulphate of ammonium and precipitated phosphate, in favour of a highly odoriferous, exceedingly valueless manure, such as, say, scutch, which consists usually of a little bone and hair, and a great deal of water, dirt, putrefaction, and stink. A writer on the subject says, "It is certainly difficult to put down the pecuniary cost of a stink, but if the farmer will take the value of one half of the food, the loss of his cattle, the amount of his farrier's bill, and to these add the cost of medicine and attendance rendered necessary by the sickness of himself, his wife, and family, and divide the gross amount by two, after adding about 25 per cent for loss of time and labour, he will arrive at something like the cost of this most expensive and fondly cherished fallacy."

A manure may be very rich in all the elements of nutrition, and yet not have the slightest odour. The smell is a sign of putrefaction, and generally means loss of ammonia, one of the most valuable constituents in a fertilizer. The ordinary farmyard manure, the litter and excrements of the cattle, is a very valuable fertilizer, and would be much more so, if the farmer had not such a fondness for a stink. I have no hesitation in saying that in many cases more than half the value of the manure is going away in that smell which so pleases the farmer's olfactory nerves, and which is so detrimental to the health of himself, his household, and his stock. Not content with losing the ammonia which escapes as gas into the air, he often places his midden in the open yard, and makes a channel running from it to an open ditch so that all the liquid portion flows away and when the rain comes, it washes away into the ditch a great portion of the ammonia which has escaped vaporization. He probably also has, in the same yard, the well which supplies his house with water. The wasted nitrogenous compounds, so beneficial to the plant, so injurious to the animal, find their way into the water of the well, which water the family drink, and thus plant the seeds of typhoid and other putrid fevers.

I incline to Alderman Mechi's theory that the dunghill ought not to be allowed to decompose in the farmyard, but should be carted straight to the land, and ploughed in, or if not at once, as soon as possible, and allow the decomposition to proceed in the soil.

But if the decomposition is to proceed on the premises, it should certainly be done under cover, in a shed with a false-bottom floor, most perfectly cemented, so as to retain the liquid portion, which is exceedingly valuable, and so keep it from running to waste, and injuring the health of the family and stock by contaminating the air and the water they have to drink. I think a little acid should also be placed on the lower floor of the shed to combine with any free ammonia.

If the farmer took adequate means for preventing the loss of the natural fertilizers produced in his own farmyard, and used these in the right season and the proper manner, he would not need to so often have recourse to the dealer, but could benefit his land by restoring to it a portion of the actual substances which had been abstracted from it. But the loss cannot, of course, be altogether made up, however careful he may be to prevent waste, for a large amount of matter is taken off the farm in the produce and stock which he sells, and in the food which the household have consumed for their sustenance. This loss must be made up by artificial fertilizers, and it was my intention to enter into the consideration of those which are now in the market, and to discuss their different advantages and disadvantages, but the necessary introduction to this subject has lengthened itself so much that I must defer their consideration to a future meeting.—*Pharmaceutical Journal.*

LIBERIAN COFFEE.

REPORT BY CONSUL-GENERAL SMYTH, OF MONROVIA.

The description of the coffee tree generally will, with the exceptions hereafter named, apply to the Liberian variety. * * * * *

The exceptions which the Liberian coffee forms to the above description, and which constitute it distinctively, a variety, are:—

1. *Its unusual size.*—Wild trees are found in the forest more than 30 feet high, and 10 to 12 inches in diameter. So, also, the cultivated tree exceeds in size that of any other variety.

2. *Its tendency to vary in the number of primary and secondary branches.*—With the Liberian coffee tree generally the branches are arranged in pairs; but occasionally one sees a single primary branch shooting from the trunk, and sometimes a single secondary one. Sometimes, also, three primary branches shoot out from one node and three secondary branches.

3. *The size and color of the berry.*—In size, both the cultivated and the wild Liberian coffee exceed that of any other known variety. Some berries from a wild tree in the section of country beyond Careysburg, about forty miles from the sea, were found to be one-third larger than any hitherto discovered. As a rule, the berries are entirely red when ripe; but some are red on one-half and yellow on the other. Some are read on one-half and green on the other. Others, when ripe are entirely green on the outside, but have the blood-red color on the inside of the first hull. Others, again, are enttrely yellow,

4. *The characteristics of the flower.*—In other countries the coffee tree belongs to the class and order *Pentandria Monogynia*. But while the Liberian coffee tree belongs to the order *Monogynia*, its class varies considerably. It may be described as belonging to the classes and order, *Pent-, Sex-, Sept-, Oct-, Non-, Dec-andria Monogynia;* that is, on the same tree there will be flowers belonging to several classes. The flowers most frequently met with are those of seven and eight segments and stamens. (This tendency to vary in the flower seems to point to the conclusion that the Liberian coffee will degenerate when removed from its *habitat*. This seems borne out by facts, for while in Java, Ceylon, and other countries, Liberian coffee has been produced exceeding in size the coffee of those respective countries, it has always lacked the superior quality of the coffee produced in Liberia and without attaining the full size.)

5. *The divisions of the berry in to sections or "beans."*—Here there is the pea-berry coffee, as in other countries, where one of the beans is fully developed and round like a pea, while the other is abortive. Then occasionally the berry is divided into three beans. Some years ago a gentleman from Careysburg showed the writer two berries of enormous size. On removing the cherry-hull there were seven sections or divisions in each cherry, like the sections of an orange or lime, but the divisions exceeding two are rare.

The virtues attributed to coffee generally are possessed in a higher degree by the Liberian variety, it being of superior quality and strength. It is an excellent beverage in heat or cold, in rainy or dry weather. It prevents the disagreeable effects of over-exertion or fatigue, and the too rapid waste of the body. It is said to possess, also, febrifuge properties, being allied to the family of the *Cinchonaceæ;* and this virtue is contained in the leaf as well as in the fruit. The coffee tree is admirably suited to the malarious districts of the coast, not only absorbing malaria with its broad leaves, but also alleviating or expelling fever by the decoction of its leaves.

As to the origin of the Liberia coffee, opinions at first varied, some supposing it to be indigenous, others thought

it was brought here by the Portuguese in remote times and had become acclimated; but at present the opinion prevails that the Liberia coffee is a native of the country. The reasons for this opinion are—

1. There is no coffee found in any other country of the world, or in any other part of Africa, like this variety. There is a coffee here, the long-pointed kind from San Domingo; but the Liberia coffee is confined strictly to the section of country included between 4° and 7° north latitude.

2. It has been found wild from the sea-shore to the section where the mountainous or hilly land descends into the grassy plains on the borders of the Mandingo country. Here the Liberia coffee apparently stops. It has not been found east of this line; nor has it been discovered at Sierra Leone on the north, or below Cape Palmas on the south. In either direction, one meets a coffee of smaller size and inferior quality.

3. The wild coffee is little inferior to the cultivated kind, and, in the instance referred to above, coffee has been found wild in the forest larger than that cultivated.

SOILS BEST SUITED TO ITS GROWTH.

The coffee tree delights most in hilly regions, although found in other situations. In Liberia, while grown in all varieties of soil, it prospers most in soils of a loose nature, such as the sandy and loamy soils, especially if these are strengthened by the addition of rocks. There are two species of sandy soil in Liberia. One has been the bed of the sea most recently. This soil has not been enriched by decayed vegetable and other matter. Its substratum of clay or other earth is at too great a depth to be of service to it; and hence it is barren, or nearly so. The other sandy soil has been somewhat enriched by decayed vegetable and other matter. It has near the surface a substratum of clay. This serves as a reservoir to hold the surplus water, which, rising through the sand by capillary attraction, keeps plants growing even in dry weather. This soil is suited to coffee, which grows rapidly in it.

But the soil which must be selected for the coffee plantations, owing to the abundance and superior quality of land of this nature, is to be found on the granitic and thickly wooded hills of the interior and the plains that surround them. These begin their ascent not far from the coast. Their soil is loam, generally intermixed with ferruginous gravel and granite rocks. Gneiss, oxide of iron, feldspar, tourmalin, and other minerals abound in some localities. In some places the granite is more friable than that near the coast, and the fertility of the soil is, to a considerable extent, maintained by the disintegration of the rock. Where the soil does not consist of "hungry gravel," but has a due proportion of loam and gravel and small stones, and this mixture extends to a considerable depth, it is rich and porous. The surplus water, instead of being carried off by "wash," which causes so much damage to land, sinks through the porous soil. On one occasion the writer was surprised to see, at an inland town, some vegetables growing on the steep face of a hill. Remarking that on his farm plants would not thrive in that situation without terracing, and inquiring what became of the surplus rain-water, he was shown the water trickling through the soil at the base of the hill.

But the coffee tree delights especially in a situation among granite rocks. Here the roots seize with avidity the surrounding rocks, and, probably by catalytic force, derive more nutriment than by the ordinary wear of the rock. The potash obtained by disintegration of the feldspar is most beneficial to it. It is in such situations that the Liberia coffee acquires that superior flavour that it is not equaled by any other coffee on the globe. On low lands the largest berry and largest crops are produced; but it is to the dry, rocky hills one must look for finest quality.

TEMPERATURE.

Situated between latitudes 4° and 8° north, for the production of the finest coffee the climate of Liberia is unsurpassed. The temperature ranges from 74° to 88° Fahr., in the shade. It occasionally reaches 90°. The lowest observed in Monrovia was during the prevalence of the harmattan winds in the month of January, when the thermometer stood 62° Fahr. at sunrise. The range is not so high in the interior, as the land rises rapidly. About 25 miles from the coast the land in some places is 550 feet above sea-level; and at the distance of 198 miles from the coast it is 2,200 feet. But notwithstanding this difference of altitude the coffee is of the same superior quality wherever found, whether it be near the sea or in the interior *cæteris paribus*. Our long, dry season tends to mature the bean thoroughly and develop its peculiar aroma.

METHOD OF CULTIVATION.

The method of cultivation is somewhat similar to that adopted in the East Indies. The forests are cleared in the same manner. The undergrowth is first cut, then the large trees are felled, lopped, and, when sufficiently dry, the whole is set on fire. The stumps of the trees are sometimes immediately removed, but not always. Most of these rot after a few years. The entire ground is not plowed or dug up; but holes are dug at proper intervals for the reception of the plants. These should not be less than 12 feet apart, and should be dug in straight parallel lines. Plowing, by loosening the soil, would, on sloping land, render it liable to be washed away by the heavy rains. The plants are taken from the nursery when from a year to two years old. Plants a year old grow faster than older ones.

In planting, the cherry hull is removed, and the seeds are deposited in the nursery in rows 2 to 3 feet apart, and 3 to 4 inches apart in the rows. They can be thinned out when large enough. The seeds are inserted in the ground at a depth of 1 inch, if the showers are regular; but if the weather be dry, then 2 inches. The transplanting is best done at the beginning of the rainy season, in May and June, for then the plants have the entire rainy season to grow and get a good start before the "dries" set in.

The Liberia coffee tree does not need shading. Of a harder nature than any other coffee, it is able to endure the tropical sun. The plants in the nursery must be shaded or mulched during the dry months. The young plants also must be mulched in the dry season, until they are large enough to shade their roots with their own foliage. In Liberia, the coffee tree does not produce largely under shade. In dry weather shade is beneficial to its roots, but the leaves must have the sunshine, to elaborate a due proportion of sap into fruit buds.

The trees are topped at 5 feet height. This rule is not observed by all the farmers. But topping increases the production of fruit, enables the fruit to be gathered more easily and with less damage to the tree. After having been topped the trees shoot out a number of suckers from the body. These should be pulled off by hand; and no secondaries should be allowed to grow on the primary branches nearer to the trunk than 18 inches. This would give an open space of 3 feet in diameter in the centre of the tree for the penetration of sunshine, and for the circulation of air. The trees should be regularly pruned. But if they are properly handled at first, severe pruning will not be necessary.

The Liberia coffee tree does not produce all its flowers at one blooming. The time of blossoming depends upon the occasional showers that fall in the dry season. For, notwithstanding the blossom buds may stand out prominently, they will remain without opening for a space of two months, or until there falls a shower of rain sufficient to saturate the soil. A light shower, that does not soak the ground, will not cause them to open. There is a light blossom in December. The fullest blooms occur in January and February; trees that are cultivated produce blossoms and fruit throughout the year. There is, however, only one full crop, and this is gathered during the months of December, January, February, and March. The cause of the crop requiring so long a time to be gathered arises from the fact that the crop does not ripen at once.

The berries are of different colors when ripe, as stated above, but the red color greatly predominates. It is the rule; the others are the exceptions.

Surface manuring is best suited to the Liberia coffee tree, as it belongs to the class of forest trees whose feeders keep near the surface. Even where the manure is placed in trenches the fibrous roots or feeders penetrate it and seek the surface long before the manure is consumed, seeking air and sunshine, which they need as well as

food. Besides, in digging trenches, there is danger of cutting off the spongioles, and thus retarding the growth of the tree.

The coffee pulp, mixed with cattle dung, forms an excellent manure. Guano has been tried with beneficial effects, but as it is very stimulating it should not be used too frequently, and should be alternated with other manures. Ashes, except on new soils, and occasionally a little lime, are of advantage to the tree. The clay from the hills of the *Termites*, or "*Bug-a-bugs*," especially on very light soils, is a good manure. Containing alumina, it prevents the too rapid evaporation of moisture and dissipation of ammonia; and having been moistened with the fluid from the bodies of the insects, it doubtless contains some uric acid, or other nitrogenous compound. It is a fact that plants of all kinds grow luxuriantly and produce abundantly when planted at the base of these hills.

But it is a mistake to stimulate the trees to heavy bearing beyond their age. This sometimes kills the trees, and when they do not die they are sickly, and require a long lime to recover.

There are two methods of hulling the coffee. One is taking off the cherry hull when fresh from the tree, drying the bean, and then denuding it of its parchment hull. The other is drying the entire berry, and taking off both hulls by one manipulation. The former method is the more expeditious. By the latter there is an improvement in the quality of the coffee, as the beans having been thoroughly dried in both hulls, the peculiar aroma is prevented from escaping. Some say there is also a gain in the weight of the bean; but the coffee is large and tough, and cannot be hulled so rapidly as by the former method. Besides, the two hulls, on drying, adhere together, and are as heavy as the small grain, and it is difficult to winnow them without a waste of the lighter grains of coffee. Then there is to be taken into consideration the long time the coffee requires for drying.

DISEASES.

The Liberia coffee tree is not subject to so many diseases as is that of other countries. There are sometimes observable on the leaves of some trees small yellow spots, which some Ceylon planters, and for a while, the writer, supposed to be *Hemileia vastatrix*, that pestilence so destructive to coffee plantations in the East Indies. But these spots were found always of the same color, and did not turn black, nor did the leaves drop off, as in the case of the above-named disease, and the trees bore their usual quantity of fruit. Near the woods, where, in other countries, this disease loves to lurk, a few trees have been found with black spots, and the green berries dried up on the trees; but the trees appeared otherwise flourishing.

The borer only occasionally attacks the coffee tree in Liberia. This is the larva of a fly or winged beetle, now identified as the *Xylotrechus quadrupes*. It generally attacks the tree some inches above the ground, and, boring a hole as round as that made by a gimlet, it ascends. The tree soon begins to droop, and finally dies, down to where the borer entered. Sometimes the borer ascends from the tap-root, in which case the entire tree dies. It usually works upward; but the writer once detected six borers starting from the same point, three them working upward and three downward.

There is a disease that affects the bark of the coffee tree. Sometimes it attacks and destroys only a single branch, at other times it destroys a half or the whole of a tree. In any case, the diseased branch or tree is drooping a long time before it expires. Trees are known to droop for more than a year before dying out. The sap-bark by degrees becomes desiccated, and turns brown. Sometimes, by digging and dunging with some stimulating manure, where the disease has not made much progress, decay is arrested, and the trees after a time resume their wonted vigor. Ceylon planters say this disease is caused by grubs attacking the roots of the trees. Some planters in Liberia hold this opinion; others do not. The disease does not begin always at the root of the tree. Sometimes it appears at the mode of a branch; at other times, midway between two pairs of branches; then, again, it ascends in a long line on one side of the tree, while the bark in all other situations is perfectly sound and healthy.

In no case, however, where diseases similar to those in other countries attack the Liberia coffee tree, are their effects so general or so disastrous.

COST OF CULTIVATION.

The questions which, in the present condition of the coffee industry, are most difficult to be answered, owing mainly to unsystematic and imperfect cultivation, are, what is the cost? and what is the production per acre? On these two points, however, approximate estimates may be made.

With regard to land, immigrants receive, free of cost, 25 acres for each family, and 10 acres for each single adult. Large quantities are given as bounty to soldiers who serve in war. Government lands may be bought by citizens for a small sum, the starting price being $1 an acre for front, and 50 cents for rear, lands.

The cost of clearing coffee land may be set down at $10 an acre. Cost of plants per acre, if bought, $6; if grown by the planter in his own nursery, they can be had for one-fourth that sum. But, in buying plants, there is a saving in time of one year. Holing and planting an acre will cost $3. Weeding, the first year, if the ground is thoroughly cleared and burned at first, will be only half the cost of subsequent years. The cost of weeding after the first year may be set down at $5.50 an acre, when weeding is done after the Liberian method generally, that is, two weedings a year. If the weeding is performed constantly by the hands going over the plantation and keeping the weeds down as fast as they appear, and before they get a start, the cost will be only a little more, while there is much gain in the thriftness of the tree. There will be no cost for topping or pruning the first year. About the third year after the trees are planted there will be a cost of $1.50 an acre for topping and handling; and, in subsequent years, the cost of pruning, $1.50 an acre, must be added to this. If the soil be very fertile, there will be no need of manure for several years, until after the trees have borne one or two good crops. If the land be sloping, and much subject to "wash," there must be an additional expense for surface trenching, or terracing.

There is no account, in the above estimates, of tools, buildings, machinery, or superintendence. The cost of these will depend on the taste and ability of the proprietor. The cost will be always in inverse proportion to the quantity of land cultivated.

The cost of picking and preparing coffee for market with the imperfect machinery at present employed, is from 2½ to 3 cents a pound—one-half of which is for picking. This is expensive. Where, however, coffee is produced on a large scale, and manipulated with improved machinery, the cost of preparing for market is much less.

PRODUCE PER TREE AND PER ACRE.

Different estimates have been given of the produce of the Liberia coffee tree. Some state that the trees, if properly cultivated, ought to average three pounds when ten or twelve years old. Others give a higher estimate. The trees in Liberia, owing to lack of means to give them that high cultivation which they require, do not give on an average one-third of the quantity of coffee they are capable of producing. The highest average on any farm has been one pound to the tree. But the trees were of all ages from three years to thirteen. Averaging the ages of the trees, this would be one pound to the tree of eight years, while proper cultivation would have given three pounds. Single trees at eight years have been known to produce five pounds. Six bushels of berries (equivalent to thirty-six pounds of dry, marketable coffee) have been gathered from a single tree. But the tree was old, well manured, and no grass was allowed to grow. The late Dutch consul informed the writer that he gathered, as the produce of two seasons, 220 pounds of coffee from eight trees growing in his yard at Sinou. These are old trees. A Ceylon coffee planter of thirty years' experience in coffee growing, estimates that the produce of an acre of Liberia coffee would, under favorable circumstances, equal that of ten acres of Ceylon coffee.

Now, allowing for overestimates, as well as for small returns from insufficient cultivation, the produce of an acre of Liberia coffee trees ten years old, *properly cultivated*, may safely be set down at 1,500 pounds. Generally, the smaller farms give a higher average than the larger ones;

pointing to the fact that the means of the farmers are insufficient to give all their trees the cultivation they need.

It is a mistake to suppose one obtains a crop from trees three years old. The trees begin to blossom in the third year, and the fruit ripens in the fourth year—each tree producing only a few berries.

In other countries the coffee-tree arrives at maturity long before it does in Liberia. This arises from the fact that the Liberian variety, being larger and hardier, takes a proportionate time to mature.

HINDERANCES TO LARGELY INCREASED PRODUCTIONS.

The export of coffee from Liberia the last season was a little more than 300,000 pounds. Considering the productiveness of the Liberian variety, the fertile soil and genial climate, one would naturally be surprised to see so small a quantity of coffee produced for exportation. But it must be borne in mind that the settlers did not on their first arrival enter largely into agriculture. Their numbers were small, and their means still more limited. Besides, they were drawn away from this noble and profitable employment by the seductions of trade. And although their attention was early called to the advantages of coffee culture, it is only in recent years that any coffee farms have been started. Even now, when the people have so generally begun the cultivation of coffee, the results are not what might be expected.

In the first place, the farms are small; and, as has been stated above, the trees on each farm have not been planted at once, they are of all ages and sizes. Then, again, the trees planted do not receive that thorough cultivation which increased means on the part of the farmers would allow. This want of capital is one of the greatest drawbacks to success in Liberia. There has been no colony, in ancient or modern times, planted and sustained with so small an expenditure of money as has been the colony of Liberia. There are no banks in the country; no institutions from which, on good security, farmers can obtain sufficient means for conducting large and profitable operations, or for rendering more profitable the smaller enterprises already undertaken.

The smallness of the number of the civilized population engaged in coffee growing is another cause of the crop not being larger. There is a population available, strong and laborious, whose efforts ought long ago to have been turned in this direction, that is, the native population. Their habits of farming are not settled. Moving from spot to spot yearly, they destroy a vast quantity of the most valuable timber. If the premiums given some years ago by the Liberian Government had been expended on native producers instead of on the civilized settlers who already appreciated the advantages of coffee culture; and if the government had announced and pursued a settled policy to prevent the wars that often rage in the country, the results would, doubtless, have been astonishingly beneficial.

In reckoning the hinderances to largely increased production, account must be taken of the unsystematic and unsettled condition of labor. From the coast tribes, large numbers are available for agricultural and other purposes. But there must be some agency to see that contracts made for labor are observed by both parties; and that, at the proper time, the laborers are returned to their homes. Even then, the coast tribes, who are principally traders and fishermen, are not so valuable for agricultural purposes as Pessahs, Golahs, Barlines, and other interior people who have always been devoted to agricultural pursuits. Then, again, in the case of these interior tribes, several difficulties present themselves. First, when their services are most needed, they depart for their own farms. Secondly, the wars call off from legitimate and profitable labor large numbers of men, to engage in the feuds that have for ages been destroying the aboriginal population. Could these internecine strifes be stopped, there would be enough labor available for the farms both of settlers and natives.

INTERNATIONAL.

A single American vessel last season exported nearly one-half of the coffee grown for foreign consumption. About two-thirds of the crop went to the United States. And this proportion has been steadily maintained all through the coffee industry. While European countries buy coffee largely for re-exportation, the United States purchase this commodity principally for consumption; and, therefore, paying a higher price, they will always compete successfully with other countries. Another reason for the larger exportation to America is, American manufactures and other products are especially desired by those engaged in coffee culture.

Now, it seems a mere trifle, this exportation of so small a quantity. But it must be remembered that coffee production in Liberia is in its infancy. The figures above are small; but they are—

> The baby figures of the giant mass
> Of things to come at last.

By removing the hinderances now in the way of large production, the coffee grown in Liberia would be of such a quantity as would affect American commerce for good.

The people of Liberia look in two directions for aid to bring about this desirable result. First, they look to American capitalists. They believe if some arrangement, some legal enactment could be decreed, by which the interests of capitalists could be thoroughly secured, money would be introduced into the country for the production of coffee, for manufactories, for the making of roads, and for other enterprises. They are doubtless correct in their opinion, when they think American capital can be introduced without endangering their republican institutions, and with less risk to the safety of the state than can that of any other country.

Again, the people of Liberia look to the United States Government for co-operation. Now, the writer does not wish to incur ridicule when he modestly hints that it is by encouraging the emigration of the negro population of America and their settlement in Liberia, this co-operation will be most effective. It may at first sight appear an inconsistent method of denationalizing their citizens for the United States to encourage this emigration. But on careful consideration, such a course will be found to be only in keeping with the efforts, which not only American philanthropists, but also the United States Government have always made to sustain the infant colony and republic. It would be helping to transmit *in perpetuum* those republican traditions which they have handed down to us. This help would arrive most opportunely. It would come at a time when European monarchism, with loud raps, is knocking at the do or of Liberia.

When the civilized settlements planted farther and farther in the interior shall have become numerous and strong enough to settle the wars that harass the land, labor will be settled and productive, and the natives, inclined to peaceful pursuits, will engage largely in the growing of coffee. As soon, too, as there is some security for labor, and some protection for trade, other commodities will be increased; and there will spring up a large and profitable commerce, to which the present commerce of the country bears no proportion; and, with suitable encouragement, the larger portion of this commerce will flow towards the United States.

JAMES H. SMYTH, *Consul-General.*

United States Consulate-General, Monrovia, Liberia.

OYSTER CULTURE IN ITALY.—The problem of obtaining a cheap supply of oysters appears to have been solved by the Italians. The most extensive ground of all, and that from which most of the oyster consumed in Southern Italy are obtained, is known as the "Mare Piccolo" or little sea, near Taranta. An immense number are reared here, and the consumption of the produce of these beds is estimated to average seven to eight millions annually, the price ranging from three to six lire per 100. The system of cultivation appears to be as successful as it is simple. From April to November, bundles of brushwood are submerged in outer sea, and to these the spawn is found to readily attach itself. They are afterwards raised, and those on which the tiny oysters have settled are sunk in the Mare Piccolo, where, in about two years, they attain their full size.—*Journal of the Society of Arts.* [Even in the face of Mr. Holdsworth's failure off the Ceylon coast, we cannot help asking why the pearl mussels should not be similarly cultivated.—ED.]

CEYLON AS A DEPÔT FOR SUPPLY OF PLANTING SUPERINTENDENTS AND LABOURERS:

Sinhalese Emigrating to Queensland.

Ceylon has long been acknowledged to be in the forefront of British Dependencies and tropical lands generally in the intelligence and enterprize brought to bear on her planting industries. Her numerous plantations have, during the past score of years, afforded a practical training to a much larger number of a would-be planters than can, alas! in the present time of depression, find profitable employment—or employment of any kind—within her bounds. The central position of the island and the attention drawn by local planting publications to its several industries, as well we may fairly say, as the fame of the *Ceylon Observer*, have done much to bring the Ceylon planter and estate labourer into public notice all over the world. It must be remembered that during the years of prosperity—1873-8—before any one had anticipated such a collapse of coffee crops as is experienced in the present season, we were urging in these columns with all the energy at our command, the importance of cultivating new products, more particularly cinchona and tea, and catering for the needful information from every authority and in every land with which we could hold communication. During that period, the *Observer* had a Special Correspondent—the late Mr. Crüwell—travelling in Brazil and Central America; another visiting the tea districts of Assam; another examining Liberian coffee in its native habitat on the West Coast of Africa; while the experience of yet another planter was laid under contribution in reference to cocoa in Trinidad; and the Nilgiris, Darjiling and British Sikhim districts were personally visited with reference to cinchona and tea cultivation. It is no wonder, therefore, if Ceylon planters who have been so well served and, who have had the opportunity of watching and sharing in an immense variety of experiments in the cultivation of new products, should be regarded as, on the whole, at the top of their profession, and should, therefore, be in request as pioneers and instructors in other settlements where the cultivation of tropical products is engaging attention. This island has supplied Southern India with a certain number of trained planters from time to time: Wynaad, Coorg and the Nilgiris coffee districts owe their beginning to Ceylon men. The Travancore planting settlement was an offshoot from this Colony, and more lately North Peermaad has been occupied in the same way. Natal and Jamaica have attracted a few Ceylon planters; Fiji has largely availed itself of experience from the same quarter; Johore and Perak are taking a goodly number of our planters, as well as Sarawak and North Borneo; while, simultaneously, Northern Australia and North-East Queensland are coming into notice and are likely to avail themselves not only of superintendents but of labourers from Ceylon. Already a considerable number of Tamil coolies have been transferred from this island to labour on Johore plantations, and although fault was found at the time with a movement which seemed to be a breach of the agreement between the local and Indian Governments; yet we are not clear that if any Ceylon-born coolies—of whom there is now a considerable population—are selected for emigrants, any infraction of the law will take place.

But it is not the emigration to other tropical lands of Tamil coolies—whether born in Ceylon or India—that we have to notice today, but the approaching departure of as many as 100 Sinhalese (carpenters and agricultural labourers) on an engagement with a Sugar-estate proprietor in Northern Queensland, an engagement which we have no doubt is the one referred to in the following article from the *Queenslander*—an extract of special interest in itself, to the people of Ceylon:—

"The cooly question has assumed a new phase. It would appear from the letter of our Maryborough correspondent, published in another column, that Mr. Nott, of Bundaberg, has resolved to cut the Gordian knot and himself import 100 Sinhalese labourers under engagement for five years, at a salary of £20 per annum, including, it may be presumed, rations and accommodation. This, by comparison with the rates paid to Polynesians and coolies, is very high, but possibly these people being in a sense skilled labourers are deemed to be of more value than either Polynesians or coolies in their primitive condition. The population of Ceylon in 1878 was 2,606,930, of whom 14,000 or 15,000 were British and other whites of European descent, about 1,750,000 Sinhalese, and the remainder Tamils, Arabs, and Malays. "The Sinhalese inhabiting the coasts are a mild, timid race, obsequious to strangers, and hospitable and humane. Their stature is rather below the middle size; their limbs slender but well shaped, eyes dark, finely-cut features, hair long, smooth, and black, turned up and fixed with a tortoiseshell comb on the top of the head. The Sinhalese of the interior, or Kandyan Sinhalese, are a superior race, being handsomer, and of more manly and independent bearing, with a greater degree of intelligence." The foregoing is from *Blackie's Encyclopædia*, published last year. From other authories we learn that the Sinhalese, with a few exceptions, are Buddhists, by which faith "the taking of life is strictly forbidden, and falsehood, intemperance, dishonesty, anger, pride and covetousness are denounced as incompatible with religion, which enjoins the practice of chastity, gratitude, contentment, moderation, forgiveness of injuries, patience, and cheerfulness" These labourers have probably been engaged in the cultivation of tobacco, cinnamon, coffee, cinchona, &c., and will no doubt be found very useful in the early efforts of our planters to raise tropical products. But the introduction of these people is likely to involve social difficulties nevertheless. They are British subjects, and in making engagements for service in Queensland will apparently not be in any way interfered with by a paternal Government. Under our Masters and Servants Act, the five years' engagements with these labourers will be valid in Queensland, and the law will treat them in all respects as it treats European labourers. Yet these people will enjoy no political rights, and will be an alien race brought into close intercourse with British colonists. Should the planters persist in introducing Sinhalese, speedy legislation will be imperative, even if the Government should determine to abandon or find themselves unable to legalise cooly immigration. It seems probable that if prohibitory legislation is not demanded by the constituencies, some restrictions at least will be imposed upon the introduction of these people, and employers will be required to pay for the privilege they enjoy. As the Sinhalese are British subjects, our Legislature cannot put a poll-tax on them, especially those who come into the colony not under engagement. But with engaged labourers the conditions are different, and the Legislature will be expected to lay down very specific rules under which their introduction may be permitted."

It will be observed that the Queensland journalist considers £20 a year, *including* rations and accommodation, "very high"! What with cost of lines, medical attendance, &c., Tamil coolies on Ceylon estates cost nearly as much as this, at least in normal seasons when there is a fair proportion of coffee crop to pick and prepare. If Mr. Nott is to get Sinhalese artificers at the rate mentioned, he certainly need not complain of it being too high, and yet we suppose out of the £20,

the Sinhalese will be able to live comfortably and save money to bring back with them to Ceylon. The experiment is in many respects a very interesting one, and no more favourable climate or land for making it, could be presented than tropical Queensland. The Sinhalese have been so accustomed to English colonists that they will soon adapt themselves to their new, if temporary, homes. Kind and considerate treatment will, of course, be necessary, and the Queenslanders will we have no doubt consider the Sinhalese in many respects more desirable servants than either South Sea Islanders or Chinese. That the call for emigrants is locally popular may be judged from the fact that Mr. Caulfeild could send 500, instead of 100 to his principal in Queensland in answer to the appeal made by advertisement in our columns. We ourselves have had a number of letters of enquiry on the subject from outstations. And yet the Sinhalese have always been regarded as an extremely conservative stay-at-home people! Perhaps the present readiness to emigrate shews how the "hard times" have told on the people, but it is also evidence of the spread of intelligence and of a more manly independent spirit. The Australian colonies too have been well spoken of among hundreds and thousands of Sinhalese through the long, pleasant and profitable business done between Australian passengers and native dealers and servants at Galle. Several Sinhalese have travelled by mail-steamers from time to time as servants, and six Sinhalese lads went as shepherds to Queensland last year who perhaps have sent back news of their comfort and good prospects which may have spread through the native villages and influenced the present movement. Be that as it may, now that emigration has commenced on a scale of some importance, we must begin to ask: is it not time for the Ceylon Government to legislate with reference to the recruitment of its subjects? It certainly behoves the local Government to see that in the lengthened engagements made, the interests of the Sinhalese are fully protected. We see it stated that a young Eurasian overseer accompanies the Sinhalese (who go by next B. I. steamer to Cooktown) with the view of settling down in the country permanently; but it is not likely that all of the emigrants will care to become permanent settlers and most will want to come home after their 2½ or 5 years' engagement. In the terms as advertized by Mr. Caulfeild, the arrangement for passage back is very fair. We quote a few paragraphs from the advestisement which are considerate and liberal:—

"Wages:—£20 sterling per annum, and house and garden 242 square yards per adult, *free*; no food, no clothing. These latter can be supplied by employer on a corresponding reduction of salary.—Passage and food:—On a five (5) years' engagement passage will be paid to and fro. On a two-and-a-half (2½) year engagement passage will be paid to and half from. Employee, on renewal of engagement for 5 years after completion of first (5) years, receives £25 per annum, wages.—Bonus of £6 Sterling: On completion of five (5) years term and employee electing to renew for a further period of five (5) years, he will be entitled to the above bonus of £6; and passage on completion of renewed term.—Bonus of £3 Sterling:—On completion of two-and a-half (2½) years term and employee electing to renew for a further portion of two-and-a-half (2½) years he will be entitled to the above £3, but has then no claim for passage money on expiry of renewed term.—Accommodation:—Same as accustomed to on the Ceylon coffee estates.—Inducements:—242 square yards of land to each adult man or woman for garden cultivation, the same not transferable without employer's sanction.—Medical attendance: Free.—Holidays and Sundays:—Sundays, Government holidays and Sinhalese holidays will be allowed.—Illness of employee:—During a prolonged or severe illness the employee will be entitled to half salary and food gratis, on doctor's certificate."

There are other clauses equally considerate, and we are told that the engagements made will come under the Labor Ordinance of Queensland; but it is obviously needful to see that the provisions of that ordinance apply to the case of Sinhalese and equally that a corresponding ordinance—if not an intercolonial enactment—be arranged for in Ceylon.

We must not be understood as wishing to discourage the present movement: we believe Ceylon and the Sinhalese will greatly profit in many ways from a few hundreds or even thousands of the people going forth to see the world and to give of their industrial power to the development of new enterprizes. Sugar cultivation is by no means light work, and the Kanakas, who have hitherto been the mainstay of the Queensland planters, and not available in proportion to the increasing demand for cheap labour. White men, even if they could toil in the field under a tropical sun, are out of the question, for the idea of

eight hours work, eight hours play
eight hours sleep, and eight *bob* a day,—

is incompatible with the profitable cultivation of the sugarcane. It remains to be seen how the Sinhalese will answer. As carpenters and helpers about the factories, they are sure to give satisfaction, but there may just be a little doubt of their readiness to do field work; and yet we must remember that they labour for long hours and under trying circumstances in their gardens and paddy fields, and that one-half their objection to employment on our hill coffee plantations arises from dislike to be associated with the immigrant Tamil coolies on whom they have been accustomed to look down. We are hopeful therefore that in Queensland Mr. Caulfeild's selection of 100 Sinhalese will give satisfaction to their employers, that they will prosper under their engagements and return in due season not only richer but better men ready to promote the development of agricultural industry, where there is abundance of scope, in their native land.

SPRING VALLEY COFFEE COMPANY, LIMITED.

Report to be presented to the Seventeenth Ordinary General Meeting of the Company, on Thursday, the 3rd day of August, 1882, at 1·30 p. m.

The Balance Sheet now submitted to you shews the financial position of the Company on 31st May, 1882; and the profit and loss account gives the result of the season of 1880-81. At the meeting held in July, 1881, you were informed that the crop then being gathered was likely to reach 6,700 cwt; but, as has been stated by circular in January last the pickings fell away at the end of the season in a manner for which your Directors were certainly not prepared; and whether too sanguine an estimate had been at first made on the spot, or the trees, sufferiug from reapeated attacks of leaf-disease, failed in a larger measure than in previous seasons to ripen the crop, the out-turn, including inferior coffee sold in Ceylon, was from the two poperties but 6,211 cwt. The amount realized from the sale of this has been £21,211 3s. 7d., and it may here be pointed out that this is within a few pounds of the sum produced by the much smaller crop of 1878-79, prices having materially receded in the meantime.

The expenditure of the year in Ceylon, which includes a considerable outlay on buildings upon Spring Valley, has been £17,485 15s. 7d., a large portion of which had been incurred before the falling off in crop was ascertained. The net result of the year's working is a profit of £2,399 7s., and this added to the balance of £1,544 16s. 1d., carried forward last year, gives £3,944 3s. 1d., to the credit of revenue. In January last a dividend of 4s. per share, or 2 per cent., upon the Capital, was paid to you, absorbing £1,600 of this credit balance. It is with much disappointment that the Board ask you to consider that payment as final for the current year, leaving £2,314 3s. 1d. to be carried forward. They would willingly recommend a further distribution at this time, if the returns for 1881-82 were likely to add materially to the balance in hand,

but the crop now shipping is in a large measure a failure on many parts of the property, the Autumn pickings having amounted to a few cwt. only, and the entire yield of the year will probably not exceed 3,000 cwt.

Believing that the best care and attention have been bestowed on the cultivation of the estate by the Company's Manager and his assistants, and knowing that outlay on what should be productive cultivation has not been spared, your directors can only attribute the shortcomings of the two years under review to the unfavourable seasons which, while they have proved antagonistic to the maturing of fruit from blossom, have developed the spores of leaf-disease in a cruelly prolific manner. The latest advices from the estate, however, report an abundant show of healthy wood, and good prospects for spring crop in 1883; and it is satisfactory to know that the trees shew no sign of succumbing to the disease, but are generally healthy and vigorous. The planting of cinchona trees on Spring Valley is being largely extended, and their growth is reported to be very encouraging for the future. During the current year bark is being scraped from some of the earlier planted trees; and, year by year, increased revenue may be looked for from this source.

It will be noticed that a sum of £868 7s. 7d. appears in the Balance Sheet as expended on the purchase and shipment of wire tramways. These are in course of erection. The transport of manure to the higher fields, so essential to the upkeep of the property, has hitherto been found impracticable, but by the suspended rope system, as now to be extended and perfected, considerable accumulations of manure from the main cattle establishment will be distributed over a large area of the property.

It is much to be regretted that the strong representations which have been made to Government in the Colony and at home, on the necessity for granting railway facilities to planters in the Ouvah district, have as yet been made in vain. To this Company alone it may safely be said that direct communication by rail to the shipping port would ensure a saving of several thousands of pounds annually, and to the Government themselves, as owners of the entire railway system of the colony, the advantage of bringing into it one of the most important sections of the island's traffic ought to be self-evident.

PROSPECTS FOR EX-CEYLON COLONISTS IN AUSTRALIA.

In answer to an enquiry made by us on behalf of a Ceylon planter with a little capital and a big family, a gentleman of wide observation and commercial experience resident in Victoria, gives the following opinion as to the best opening in the Colonies. The information may be of service to others who may be meditating settlement in the far South on removal from depressed, overcrowded Ceylon:—"My own idea is Victoria or New Zealand will be the best place for anyone with limited means. What is the age of the sons, and what kind of work are they used to? Probably the best employment in Victoria would be dairy farming, but this is very laborious. Wheat growing is easier but risky, but still a friend of mine has just netted £2.000 off 600 acres of land. Victoria has the advantage of a good market, which *none* of the other colonies can boast about. Tasmania I look upon as only suitable to the miner and capitalist. New Zealand has good climate and land, but a very bad market for her produce." Our correspondent promises to give fuller particulars by next mail.

INDIARUBBER PRODUCTION IN BRAZIL.

A pamphlet, lately issued in Rio de Janeiro by Senhor Pimenta Bueno, calls attention to the great importance of this product, and the influence it has had on the commerce of Para, the value of whose imports and exports has risen from 26,352,580 mils. during the years 1849-1854, to, in 1874-1879, 108,702,684 mils. or fully four times as much during the last five years, while the revenue of the city has increased during the same period from 4,368.527,650 reis to 17,825,895,567 reis, having during the five years previously, say from 1869 to 1874, reached the large sum of 21,245 591 032 reis. To show the proportionate value of indiarubber, as compared with other exports, the return for 1879 80 apportions them as follows:—

Indiarubber	...	12,242 500 mils.
Castanhanuts	...	1,473,800 ,,
Cocoa	...	1,032,500 ,,
		14,748,800 ,,

On the other hand, the total export from the two provinces of Para and Amazonas during the same period was 15,497,600 mils., a striking proof of the position held by indiarubber. It is further stated that "the provinces of Para and the Amazonas import sugar, coffee, Indian corn, beans, and even mandioca flour!" Again, the writer of the pamphlet states that indiarubber occupies the third place in the exports of the Empire, after coffee and sugar, and yet how few of our readers are probably aware of this fact, Para occupying the extreme northern limits of the Empire, with its vast river, the Amazon, flowing past it.

The writer shows how, owing to the destructive manner in which the indiarubber trees are cut down this valuable branch of industry is threatened with serious diminution, if not almost extinction, and urges that means ought to be taken to regulate the cultivation and supply of this valuable article, a conclusion in which most people must agree, who feel an interest in Brazil, as well as the great river which gives access from Para to the Andes, and whose banks are covered with primeval forests, many as yet almost untrodden by the foot of man. A great increase in the value of the article is exhibited, that current being 3,100 reis per kilogram for fine quality, whereas in the year 1825 it was only worth 300 reis the kilogram. It may also be noticed that indiarubber contributes 25 per cent of its value to the general and municipal taxes of Para.

The naturalist Agassiz, in his great work on Brazil, devotes a large portion of it to the Amazon and its productions, extracts from which will be found in our columns, and he makes especial mention of the attention he received from Senhor Pimenta Bueno during his visit to that region.—*South American Journal.*

FIBRES AND FIBRE MACHINERY.

The Calcutta *Englishman* summarizes information which has been published in the *Calcutta Gazette* regarding the cultivation of jute in the State of Louisiana, and which is calculated seriously to affect the cultivators of jute in India and the manufacturers of the fibre in Calcutta and Dundee. Jute as well as rameh (rhea grass) seems succeeding well. The *Englishman* article states:—

India has hitherto supplied jute to all manufacturing countries. The importance of jute cultivation to the cotton planter of the Southern States of America is very great. Jute butts imported at a low rate of duty have, it is said, driven bagging flax to the wall. In 1879 the estimated yards of bagging used to cover the cotton crops of the year was 33,000,000. Of this quantity 28 000,000 yards were made of jute butts and "rejections" and the balance, 5 00 0,000, of flax straw. Flax bagging, it appears is not in favour as compared with jute butts bagging as it is so dirty that it makes a difference in the price of the cotton. Since 1872, when Congress took off the duty on jute, it has been found impossible at a paying rate to manufacture bagging for cotton in the State of Minnesota; and thousands

of dollars worth of fibre in Wisconsin and Minnesota are represented as "rotting upon the fields." No use of the vast acreage of flax fibre is made, except in one establishment, in the State. The same condition of affairs was apparent in other states of the Union when the duty on gunny cloth was reduced to such an extent as to make the manufacture of flax for bagging purposes impossible.

We should think that in such a case the flax straw could be utilized for paper-making. While it is stated that there can be no doubt as to the successful cultivation of jute, it is added that a machine has been invented such as the Indian Government desiderated in the case of rhea, and for which, if perfectly successful, a prize of R50 000 was to be awarded. No machine fulfilling all the conditions was brought forward, although some did good work. Now, however, we are told that:—

With regard to the separation of the fibre from the bark a process has, it appears, been discovered, a combination of chemical and mechanical means, by which the "intrinsic and industrial value of jute can be greatly enhanced at comparatively small cost." This however requires to be confirmed by the test of practical experience. In this newly discovered process the steeping and rolling of the plant hitherto deemed indispensible has been overcome and the cultivator of jute need have no more difficulty with his jute crop than with wheat or rye. Sowing, cutting and carting will represent the cultivator's work, and pools for steeping as in India for jute and ramie, and for flax in various countries in Europe, with the various handlings and dryings entailed will now, should the invention bear the test of experience, be unnecessary. In addition to this, a machine of a most remarkable character has been invented and patented in America by Messrs. Martin Dennis and Albert Angell for the preparation of jute or ramie fibre. It is thus described by Mr. Drummond.

This machine is 34 inches wide and 44 inches high, and is very strong and not liable to damage. It can be removed to any point without taking apart, and it is ready for use on the instant, being simply a series of rollers, and scrapers and beaters. At the top is a copper with a dozen holes, through which the fibre is fed to the machine. The machine started, a stalk of ramie or other fibre is set by the thick end into the hole; it is grasped between two rollers covered with flexible rubber, and the stalk in passing into the machine immediately encounters a knife, which splits it in two, sending the two halves to opposite sides of the machine. The halves on their journey encounter "beaters," which break off the pith and wood, and, on the other side, encounter "scrapers" which remove the bark, and in an instant the filament comes out in long ribbons of fibre. An unbroken ribbon, exactly the length of the stalk or switch which was fed to the machine, is thus obtained, and the wood and extraneous matter are as cleanly taken off as could be desired and without slivers.

This machine claims to be able to clean or prepare 2,000 lb. of fibre a day, and that it may be fed by a boy. Ramie, mallow, or jute may be run through it as soon as they are cut without any rotting of the outer bark by steeping, which, it is contended, injures the fibre. The fibre is unbroken. The scrapings can be used as paper stock, and the woody fibre as fuel for driving the machine. The only process needful after running the jute through the machine is to boil the gum from the ribbons of fibre, and they are then ready to be tied in hanks for the manufacturers. The very great importance of the inventions we have thus shortly noticed cannot be overestimated that is, should they prove equal to all the work they claim to be able to perform. Messrs. Dennis and Angell's machine is about to be tested on a large scale during the year, and we may look for reports of its working in a month or two. Should, however, the operations prove successful, the Indian cultivator and the Dundee manufacturers of jute will have to adapt themselves to the changed conditions of cultivation and manufacture if they are to compete with America. There is always the advantage of cheap labour on the side of India and if America invent machines European capital and enterprize can procure and work them with the advantage of an almost unlimited and cheap labour market thrown into the bargain. How it will affect Dundee or India remains to be seen.

Of course the success of the semi-chemical process, and that of the machine, might help to render the extraction of fibre from rhea and other plants including plaintains, aloes, pineapples, &c., profitable in Ceylon.

COFFEE AND TEA CULTIVATION IN THE MADRAS PRESIDENCY.

A statement shewing the extent of coffee and tea cultivation in the Madras Presidency for 1881 has recently been submitted to the Government. The statements from Travancore and Cochin are still due, which is unfortunate, as Travancore has a rather large acreage under coffee cultivation. The statement illustrative of the state of coffee cultivation shews that the total number of plantations is 18,028, including 14,241 plantations in the Wynaad. This is a decrease as compared with former years, which is attributed to the abandonment of estates in consequence of the plants thereon having been blighted. Of course a large number of these are small native gardens. Elevation ranges from as low as 100 feet on the Malabar Coast to 6,000 feet on the Nilgiris. The Wynaad estates are from 2,400 to 4,700 feet above sea level. The total area in acres is as follows: Vizagapatam 6; Madura 5,059; Tinnevelly 2,870; Coimbatore 3,888; Nilgiris 48,033; Salem 10,718; Malabar (including Wynaad) 63,016; the grand total being 133,591 acres. Of this area 59,355 acres is not yet planted, although the land has been taken up for planting. The acreage for Travancore will, we believe, be found to be about 30,000 acres, making a grand total of over 160,000 acres. The average yield in lb. per acre of mature plants varies from 100lb in some parts of Malabar to 554lb. in Palni, Madura. The Nilgiris average is a good one, 426lb., much higher than that of the Wynaad, 195lb The Ceylon average of recent years, has been under 3 cwt. per acre. The total approximate yield in the Nilgiris was 10,015,619 lb., and that of the Wynaad, with a larger area planted, only about half the quantity, viz., 5,763,225 lb. The smallness of the yield in the Salem District, 792,000 lb. from 5,650 acres planted, is attributed to the damage committed by the cyclone in October last. The total approximate yield in all the districts was 18 548,646 lb. These statistics show the grave importance to this Presidency of the recent action of the British Government with regard to the adulteration of coffee, cultivation. We must now turn to the statement illustrative of the state of tea cultivation in this Presidency, is not a very elaborate one. The plantations are of course chiefly upon the Nilgiris, where they number 86; there are three small estates in the Malabar district, and two very small estates in Madura. The elevation ranges from 3,000 to 8,000 feet. The number of acres planted is 4,302, and there are 4,833 acres taken up for planting but not yet planted. The approximate yield was 648,616 lb., or about 246 lb. per acre of mature plants. Some estates—one at Coonoor—produced as much as 400 lb. per acre, we hear privately, which must have resulted from high cultivation and careful working. It must be remembered that

these returns do not include Travancore and Cochin, although the figures from these districts will not greatly affect the tea statistics of the Presidency, we suppose. We should have liked to have seen the returns more complete; some idea of the size of the estates might have been conveyed. At present a large number of very small gardens must be included, or the Wynaad estates would not be entered as numbering over 14,000 for an area of 58,652 acres of coffee.—*M. Mail.*

DEVELOPEMENT OF THE AMAZON:

SUGAR, COFFEE AND NEW PRODUCTS.

(From the *South American Journal.*)

We have for some time endeavoured to call attention to the great facilities presented by this immense inland navigation, if properly developed, and rendered more available to external commerce. In another part of our paper will be found allusion to a pamphlet lately issued by Senhor Pimenta Bueno, upon the culture of India rubber, and the evils arising from neglect of this most valuable commodity, which requires to be more under control if it is not to fall into decadence and eventual ruin from the reckless manner the trees are dealt with.

Professor Agassiz, who paid a lengthened visit to Brazil during the winter of 1865, and devoted a large portion of his interesting volume, published in 1868, to an account of an exploration of the Amazon, more extensive probably than by any writer who has preceded him as regards its facilities, thus expresses the general impression made upon him :—

"I have never been able to explain quite to my own satisfaction the somewhat melancholy impression which this region, lonely as it unquestionably is, made upon me when I first saw it—an impression not wholly destroyed by a longer residence. Perhaps it is the general aspect of incompleteness and decay, the absence of energy and enterprize making the lavish gifts of nature of no avail. In the midst of a country that should be overflowing with agricultural products neither milk nor butter, nor cheese, nor vegetables, nor fruit, are to be had. You constantly hear people complain of the difficulty of procuring the commonest articles of domestic consumption, when, in fact, they ought to be produced by every landowner. The agricultural districts of Brazil are rich and fertile, but there is no agricultural population. The tamed Indian floating about in his canoe, the only home to which he has a genuine attachment, never striking root in the soil, has no genius for cultivating the ground."

Speaking of the productions of sugar and coffee, rather a singular illustration is afforded of the want of appreciation in which Brazil coffee has been held in foreign countries to remedy which laudable efforts are now being made in this country.

Mr. Agassiz says :—"The sugar cane has long being the chief object of cultivation in Brazil, and the production of sugar is still considerable; but within several years the planting of sugar cane has given way to that of coffee. I have taken pains to ascertain the facts respecting the cultivation of coffee during the last fifty years; the immense development of this branch of industry and the rapidity of the movement, especially in a country where labour is so scarce, is amongst the most striking economical phenomena of the country. Thanks to their perseverance and to the favourable conditions presented by the constitution of their soil, the Brazilians have obtained a kind of monopoly of coffee. More than half the coffee consumed in the world is of Brazilian growth. And yet the coffee of Brazil has little reputation, and is even greatly underrated. Why is this? Simply because a great deal of the best produce of Brazilian plantations is sold under the name of Java and Mocha, or as the coffee of Martinique or Bourbon. Martinique produces only six hundred sacks of coffee annually, Guadeloupe, whose coffee is sold under the name of the neighbouring islands, yields six thousand sacks, not enough to provide the market of Rio de Janeiro for twenty-four hours, and the Island of Bourbon hardly more. A great part of the coffee which is bought under these names, or under that of Java coffee, is Brazilian, while the so called Mocha coffee is often nothing but the small round bean of the Brazilian plant found at the summit of the branches and very carefully selected. If the fazendeiro, like the Java planters, sold the crops under a special mark, the great purchasers would learn with what merchandize they have to deal, and the agriculture would be greatly benefitted. But there intervenes between the fazendeiro and the exporter a class of merchants—half bankers, half brokers—known as commissarios, who, by mixing different harvests, lower the standard of the crop, thus relieving the producer of all responsibility, and depriving the product of its true characteristics."

This state of things is about to be rectified, and hereafter Brazil coffee will stand more on its real merits.*

Professor Agassiz, after drawing striking pictures of the great advantages the Amazon valley presents to the Empire and the delusions that prevail as to the injurious nature of the climate, concludes his remarks with the following additional notice of its productions :—"The importance of the Basin of the Amazon to Brazil from an industrial point of view can hardly be over estimated. Its woods alone have an almost priceless value. Nowhere in the world is there finer timber, either for solid constructions or for works of ornament, and yet it is scarcely used even for the local buildings, and makes no part whatever of the exports. It is strange that the development of this branch of industry should not even have begun in Brazil for the rivers which flow past these magnificent forests seem meant to serve, first as a water power for the saw mills which ought to be established along their borders, and then as a means of transportation for the material so provided. Setting aside the woods as timber, what shall I say of the mass of fruit, resin, oils, colouring matter, textile fibres which they yield. When I stopped at Para, on my way to the United States, an exhibition of Amazonian products, brought together in preparation for the World's Fair at Paris, was still open. Much as I had admired, during my journey, the richness and variety of the materials native to the soil, I was amazed when I saw them side by side. I here noticed among others, a collection of no less than one hundred and seventeen kinds of highly valuable wood, cut from a piece of land less than half a mile square. Of these many were dark coloured, veined woods, susceptible of a high polish—as beautiful as rosewood or ebony. There was a great variety of oils, all remarkable for their clearness and purity. There were a number of fabrics made from the fibres of the palm, and an endless variety of fruits. An Empire might esteem itself rich in any one of the sources of industry which abound in this valley, and yet the greater part of its vast growth rots on the ground, and goes to form a little more river mud, or to stain the waters on the shores of which its manifold products die and decompose. But what surprized me most was to find that a great part of this region was favourable to the raising of cattle. Fine sheep are fed on the grassy plains and on the hills which stretch between Obydos and Almeyrim, and I have rarely eaten better mutton

* Its "real merits" will be rated in the future as they were in the past by the extent to which the "cherries" are allowed to ripen on the trees, and the care bestowed on the preparation. It has been because of beans gathered prematurely and badly prepared that Rio coffee has held low rank.—Ed.]

than at Eraré in the midst of these Serras. And yet the inhabitants of this fertile region suffer from hunger. The insufficiency of food is evident, but it arises solely from the inability of the people to avail themselves of the natural productions of soil. As an instance of this I may mention that, though living on the banks of rivers which abound in delicious fish, they make large use of salt cod, imported from other countries."

[It just comes to this: that one of the richest portions of the globe is, wrongfully, in possession of the acre least fitted to turn it to good account.—ED.]

RUST IN WHEAT.—Notwithstanding the frequent experiments made to ascertain as nearly as possible the cause of rust in wheat, no certain conclusion has yet been arrived at. The Rev. J. B. Sneyd, of South Australia, gives as his opinion, based upon his own observations, that "where limestone exists in considerable quantities in the soil, red rust does not make much havoc with the crop; where it exists only in small quantities, rust seems to flourish." —*Queenslander.*

VINES IN CALIFORNIA.—Concerning the vine culture of California, the San Francisco *Bulletin* says:—"The increase in the size of vine-yards is remarkable. Four years ago a plantation of 200 acres was considered a very large plantation. Now vineyards of 500 to 600 acres are common, and there has this year been planted one of 1,500 acres, near Los Angeles. An experienced viniculturist gives it as his opinion that before three years we shall have vineyards of 5,000 to 6,000 acres each. The present total number of acres under vines, he conjectures, is about 100,000, all of which will be bearing four years from now, with a possible production of 40,000,000 to 50 000,000 gallons yearly. Last year's vintage produced 9,000,000 gallons, but more than one-third was destroyed through frosts. The outlook for the next year's crop is very good; but last year's prices for grapes will not be maintained."—*Public Opinion.*

PAPER TEA-BOXES?—Why not, since roofing tiles, railway carriage wheels and especially casks are made of paper? The idea suggested itself to us while reading a valuable article on "Tea Bulking" in the *Indigo Planters' Gazette.* The article concludes thus:—"There is one point in connection with box-making, which seems to have escaped the notice of planters. Boxes, as a rule, are not cubes, and for many reasons they ought to be. In making boxes by machinery, it is clearly advantageous to have all the sides of similar size, but the great advantage to be gained is in stowing in a vessel's hold. A box is handed down to the stowing coolies and after being tried in a certain space, it is found that it won't fit in, the box is then lifted and twisted round till the narrowest side is ascertained, and then it is returned to its place. All this knocking about would be avoided, if it were known that tea chests were cubes, because if a chest failed to fit a space one way, it would be folly to move it about in a vain hunt for a narrower side. These are the little points—little, individually, perhaps, but powerful for evil collectively—that are as a rule not considered worth wasting time about, but which must be attended to in an intelligent manner, in view of the competition with China tea which is every day becoming more keen." Now, it seems to us that by the use of no other substance could so much uniformity of strength, size and weight be secured as papier mâché well dried, solidified by pressure, and perhaps lacquered on the outside. How the sheets of which the boxes should be made could be put together is the greatest difficulty we anticipate, but no doubt it can be overcome. Will some competent authority work out the idea, which is so obvious that, perhaps, it has already led to experiment.

TEA.—The tea trade in Madras last month was a pretty large one, the total quantity of tea shipped from this port being 21,620 lb. valued at R22,877. Of the above quantity 20,010 lb. were shipped to Great Britain, 792 lb. to New York, 738 lb. to Melbourne and 80 lb. to Rangoon. Small shipments continue to be made by every steamer leaving Madras for London. —*M. Standard.*

NEW PRODUCTS.—The "Agricultor Progressista" publishes a letter from a Brazilian engineer, directing attention to the value of the nuts of the piassaba palm as a fuel for steam engines. He declares that they are equal in heating quality to the best coal, and superior to it in that they leave no cinder—only an ash, very rich in potash. The piassaba palm abounds, and the writer calculates that ten palms would yield per annum 5,000 nuts, equivalent to a ton of coal, and that 180 palms would require only one acre. An experiment might be made on some of the Anglo-Brazilian railways.—*S. A. Journal.*

"NEW AND UNTRIED FIELDS IN CEYLON."—Under this heading, the *Lanka Snahan,* while deploring the want of originality in the Ceylonese of the present day, points out various fields to which they should turn attention. In the cultivation of paddy, the natives have gone on in the same primitive fashion for centuries, but now that Europeans have begun to take up this product, no doubt we shall see an improvement. In coconut and cinnamon cultivation Europeans have already set the example of scientific methods, and intelligent natives have not been slow to follow. But there are other fields of enterprize almost untouched. To quote from our contemporary:—"In manufactures Ceylon has made but little progress though admittedly there is extensive room for it. Many of the products of our fields gardens and forests are wasted or lie rotting in the air from our ignorance of the means of utilizing them. We have an unlimited number of fibre yielding plants the produce of which can easily be converted into cordage, canvass or cloth, but most of which is now absolutely thrown away. Our lands can produce an inexhaustible supply of different varieties of fruits and vegetables which if people are more generally conversant with the methods of preserving them, can be kept fresh and ready for daily use when the season has passed besides exporting in large quantities to foreign countries. The field for breeding every variety of cattle horses and fowls is practically without limit. If we will follow the example of the 'go-ahead' Americans the most useless lakes and lagoons can be turned it seems to very profitable account by being used for breeding the best kind of fishes the supply of which when once established will be almost everlasting. We well remember the remarks made by some Americans during the last pearl fishery, that every bit of the flesh and shells of oysters buried under ground in Ceylon, would have been converted to some use in the United States, if the fishery had only taken place there. For manufacturing and other purposes it is impossible to compete with Western nations without the introduction of suitable machinery. The use of Machinery is not in all cases so expensive as it is generally supposed in Ceylon. There are hundreds of machines which with very inconsiderable outlay, can be made to yield very large profits. Even the costly machines are in the long run of great value to their possessors. It is use of the machinery in addition to large forest land, which has made the United States in a comparatively few years a formidable rival to the long established commerce of England. Steam and machinery there have to a great extent taken manual work out of the hands of laborers." The newly formed Agricultural Association will, no doubt, make it one of its aims to introduce new enterprizes and extend and improve old ones among the natives.

Cinchona.—The advanced rates obtained for cinchona of good quality at the last public sale and the very spirited bidding are explained by our morning contemporary as follows:—"It appears that two London Firms had forwarded an opinion, based on advices of sales from this side, that the margin between the Colombo and the London rates was greater than circumstances warranted, and in order to put this to the test, orders for a good extent of bark were sent out to two local houses, who by their competition advanced the rates by about seven cents the unit of quinine, which, as our readers are aware, forms the basis of calculations for value."

Gum Leaf-disease.—With reference to this newly-developed pest, the interesting question has been incidentally suggested to us. whether the affection has ever been seen on the large *primary* foliage of the blue gums, and, if it has *not*, whether the exemption from it of trees on the Lover's Leap plantation and elsewhere may not be due to the fact that the advice which Dr. Thwaites, C.M.G., formerly gave to us and others, to keep the trees topped, so as always to preserve the original leafage, has been followed? We confess that the cause for exemption if such exemption exists. does not seem to us sufficient, but we shall be glad to have information on this and other heads from those able to afford it. The extra virulence of the attack this season seems clearly enough to be due to the excessive and incessant rainfall.

Amateur gardeners are not generally aware that sawdust has been found of great service in striking cuttings. A writer in the *Journal of Horticulture* recommended it in very strong terms some time back, and other journals, devoted to agriculture have repeated it on the experience of others, so that it appears to be an established fact in propagating at the present time. The testimony given concerning it agrees in this, that it tends to produce roots more quickly, surely, and numerously than any other material; and if the material is obtained fresh from the pits it will not require renewing for twelve months. Cuttings of soft wooded and hard wooded plants alike strike freely in it, and the kind of sawdust mostly tried in this way has been soft wood. Sawdust as a fertilizing agent is of little or no value unless bedded down to animals.—*Queenslander.*

Creoles and Coolies in British Guiana: a Stringent Act against Indolence Required.—The *Royal Gazette* says:—The first, and we might safely say, the only source of permanent wealth in a colony such as this is. lies in agriculture and its operations. Every other means of livelihood hinges on the fruits of the soil. and there is more truth than is generally credited to it in Mr. Russell's contention, that to the immigrant population should be charged the entire prosperity of the Colony, and the ability of its inhabitants to meet the taxation necessary to grease the wheels of the state, and which led to its ultimate development. Without the coolie these means would shortly be nowhere, and British Guiana would speedily revert to the deplorable position it was in prior to 1851. Could the vagrancy act only be carried out, and the lazy youths now hanging round our towns and villages, be forced to gain an honest livelihood whether on their own grounds or in the sugar estates we would speedily see a vast improvement on the face of the whole country; and the present cry of the merchants regarding dull trade would be soon changed in its tune. It is not to the coolie and his saving habits. this condition can be attributed but to the lazy creole. The sooner this fact is recognized. and pressure brought to bear upon the Government to cause each member of the community to add by his labour, the *quota* to the public weal. so much the earlier will the trade of the Colony improve and its merchants regain their former prosperous position.

Planting and Coffee Leaf Disease in the Straits.—Mr. P. H. Hill, a well known ex-Matale planter, writes by the mail:—"I am anxiously watching results of experiments with Mr Storck's vaporization cure for leaf-disease. I have tried all remedies that have been advocated while I was in Ceylon, and did not ever try one a second time. I have had Mr. Storck's system at work here since April and on Liberian trees that (they came from Ceylon) were very bad indeed in April: the results are all one could wish. I have ordered a large quantity of No. 5 acid. A nursery also has been cured here during the past four months: *that* took a long time before the carbolic had any visible effect on it. It is no use trying with any but the real acid: it it is only disappointing. 5 months is a short time and previous failures engender caution, but so far I quite think it will prove a success. There will be a large rise in the revenue here, and, if there was an *Observer* to promote, review and discuss planting matters, it would be a want supplied." Ceylon is not so far away: let the Straits planters freely utilize these columns and those of the *T. A.*, and they will find the Straits authorities carefully considering their suggestions.

Tissamaharama Tank in Ceylon is the subject of an able report by Mr. J. H. Dawson, embodied in a Sessional paper just published. His subject is really "Irrigation" under the tank in the valley of Tihawa, the conformation of which he describes. He next refers at some length to the ancient scheme for the irrigation of the valley, and Mr. Dawson sums up with the belief that these and other similar works "so generally found to be projected on scientific principles," are, "if rude in the method of their construction, admirably adapted for the achievement of the objects for which they were designed." Next we have a table of rainfall for 8 years—the extremes being 23·82 in 1876, and 73·94 in 1878—the average for 1873-80, being 46·10 inches. Then follows the more practical part of a Supply scheme from Ellagalla, Tissawewa tank, Yodayawewa tank, distribution under Tissamaharama tank, a synopsis of report and estimate of cost of works, description of plans and 'Financial.' The latter exhibits a most glowing estimate of the advantage to Government which in revenue alone should get 13½ per cent on an expenditure of R300,000! Later on, Mr. Churchill deals with Mr. Dawson's second and more modest scheme, and confirms his estimate as follows:—"The Tissamahārāma works. as they are at present, will serve to irrigate 1,500 acres of paddy land. They were originally designed on a small scale (with the exception of the anicut across the Māgam river) with the view of ascertaining whether people would go and settle down and purchase and cultivate their lands. If this has proved to be the case, I think it would be desirable that the works should be enlarged for the irrigation of 5,000 acres more land. This could be done at a cost of 52,800 rupees. Mr. Dawson, in his report,. calculates the return to the Government from one fifteen-fold crop over the extent of this 5,000 acres at 7½ per cent. on the total expenditure on the works (from the first commencement) of 200,000 rupees. This, I think, is a very low estimate of what may be expected. As the land becomes sold and cultivation extends over these 5,000 acres, the works could then be further enlarged and another reservoir formed at a cost of about 100,000 rupees for the irrigation of another 5,000 acres, the return from which would not be less than from the other 5,000 acres." But it is idle estimating and speculating at a time when the whole of the revenue is absorbed in Establishments and the mere routine motion of Government machinery. We doubt if £20,000 can be spared during 1883 out of £1,250,000, for investment in a work of a decidedly reproductive character; and yet there are gentlemen in our midst who are impatient at the cry for Retrenchment!

Sulphur.—The value of the yearly production of sulphur in Italy is now estimated at something like five million dollars. This country is the greatest importer, the next in order being France, Great Britain and Germany. The exporting ports are, Gurgenti, Licata, Terranova, and Catania. Fifty per cent of the material is lost in burning and melting, and the whole process in use is very primitive.—*Oil and Drug News.*

Artificial Quinine.—There have been rumours for some time that artificial quinine could be made, and was indeed being largely manufactured. The process was apparently one of childlike simplicity, and consisted only in bringing together dihydrolepidin, dihydroethylpyridin, and the chloranhydride of chloroprophinic acid. A substance obtained in this, or some similar way, and called chinolin tartrate or artificial quinine, has been used by Dr. Schapringer in the Jewish Hospital, Philadelphia. It was found to have slight antiperiodic properties, but to be far inferior to quinine —*Record.*

A Strong and Handy Cement.—One of the strongest cements, and very readily made, is obtained when equal quantities of gutta percha and shellac are melted together and well stirred This is best done in an iron capsule placed on a sand bath, and heated either over a gas furnace or on the top of a stove. It is a combination possessing both hardness and toughness—qualities that make it particularly desirable in mending crockery. When this cement is used the articles to be mended should be warmed to about the melting point of the mixture, and then retained in proper position until cool, when they are ready for use.—*Oil and Drug News.*

Our Forests and Vegetation.—We call attention to Mr. Vincent's paper on "Ceylon Forests," which we take over from the *Indian Quarterly Magazine of Forestry* and to the summary and translation of Professor Haeckel s enthusiastic description of what he saw and experienced in Ceylon. There is more of the latter to follow. It will be observed that Mr. Vincent expressly states that chena cultivation has perhaps done more harm to the forests in Ceylon than in any other part of the East, and more especially has the mischief been done during the past fifty years —a severe reflection on the way in which the Agents and Assistant Agents of Government have looked after their districts.

Our Hills.—We read in the *Indian World*:—"Some of the Darjeeling people are complaining about "continuous rain" up there. But continuous rain is the normal condition of things at Darjeeling. People who are not prepared to live in a mackintosh suit, should stay in the plains." The truth in this case is two-sided. A Ceylon planter visited Darjeeling and experienced incessant rain. Our experience was incessant drought which had lasted for seven months, and the view of Kinchinjunga was hidden from us, not by mist but by the smoke of a country a large portion of which had been fired by the *joomers*, or we should call them in Ceylon the *chenaers*.

A New Article of Trade.—Of late an export trade has sprung up in tamarind, and large supplies are sent by almost every P. & O. steamer to Suez and London. Supplies of tamarind obtained from the districts were hitherto retained for local consumption, and with a demand from almost all the towns on the coast, and especially in the southern districtsand Ceylon, the trade in this commodity was a purely Indian one. Now, however, with shipments steadily going forward, we may have to record the fact that the price of tamarind has risen, and that the trade in it has never been so brisk as it is present. The steamer "Nepal," on the 21st ultimo, took away 422 bundles from this port, and large supplies were shipped on board the "Lombardy" yesterday.—*Madras Standard.*

Perak.—Mr. A. Schutze, proprietor of the coffee plantation in Perak so much a dmired the other day by His Excellency Governor Weld is at present on a short visit to Ceylon, and he will be glad, during his stay at the Queen's Hotel, Kandy, till Monday next. and after that at the Grand Oriental Hotel, Colombo, till Thursday or Friday, to give information about this new planting territory, to any intending investors. Mr. Schutze brought over with him some 24 bushels of his maiden coffee crop in parchment. This on being cured in Colombo, has given the fair outturn of 5 cwt., and although the bean had been lying too long in the parchment skin, the samples (of Nos. 0 1, and P.B.) given to us by Mr. Schutze, are very favourable and of good colour. These can be seen at the *Observer* Office.

Coffee Adulteration.—We see from a paragraph in a home paper by this mail that Mr. Magniac, M.P., induced the Government to provide for other admixtures with coffee, in the same way as has been done with chicory, thus:—"*Vegetable Matter.*"—Mr. Magniac has succeeded in considerably improving the new law as to the sale of substitutes for coffee by the insertion of a clause providing that all packets purporting to contain coffee with a mixture of other articles should bear on the outside a plainly-printed statement of the nature of the admixture. The amendment was accepted by the Government, who, however, most inconsistently refused to accept another amendment proposed by Mr. Cavendish Bentinck, that the percentage of coffee to other ingredients should also be stated. The label will run no doubt: "This is a mixture of coffee and ———." But, until the proportions are specified, such label will afford little or no check on the retailers.

Cinchona Cultivation under Shade; Coffee Crops, Forest Denudation and Change of Seasons.—A planter writes:—"I should be glad to see a paragraph from some one who has had practical experience of cinchona cultivated under the shade of forest trees, but I should not consider a small patch of standing jungle, on a ridge, for instance, planted with cinchonas, any argument for or against shade. Could you get 'W. D. B.' to give us his opinion on this important subject?. I feel sure it would be of value. The summing up of his letter of the 15th on abnormal seasons I believe to be as true as any judge ever summed up a case for the consideration of a jury. If we can agree that abnormal seasons as understood by 'W. D. B.' is the cause of short crops, and if there be any truth in the theory that the wholesale destruction of our mountain forest is the cause of the change of climate. then, in addition to the means recommended by 'W. D. B.' so as to modify the evil effects of the seasons I would suggest that Government be asked to appoint two or more competent foresters from India to supervise the establishing of nurseries of suitable forest trees for the purpose of planting up the whole of the available crown patanas. Blue gums and other quick-growing trees would soon repay the trouble and expense. Our Forestry Department, I see, is composed of six foresters, but report hath it that their duties are more in the way of marking trees for the axe than for planting purposes.' Our correspondent may make his mind easy about' forest denudation in Ceylon affecting the rainfall and seasons. We think "W."'s admirable letter in Friday's *Observer* (which probably our correspondent had not read when he wrote) should once and for ever dispose of the croaking about forest denudation in Ceylon. Of course "W." does not attempt to defend indiscriminate felling of forests. Timber is one of man's wants, and forests have there rôle. However, so far as the matter bears on *our* case, it is clear we may leave it to theorists.

Correspondence.

To the Editor of the Ceylon Observer.

INFORMATION FROM PERU AND CHILÉ.

Edinburgh, 26th July 1882.

Dear Sir,—The annexed extract from a private letter received from my brother in South America may be interesting, should you care about publishing it.—Yours, &c., P. D. MILLIE.

"Coquimbo, Chilé, June 1882.

"Cinchona.—You are going to have a pretty low price for your produce, now that its cultivation is carried on, on so large a scale, almost everywhere that the tree will grow. Quinine will ere long be amazingly cheap too; all the better for mankind, if not for the planters. A letter has at last been received from the Vice-Consul at the port of Mellendo in Peru. It turns out just as I told you would be the case. No planter will sell, or allow to be taken, if he knows it, the seed of the *Calisaya Vera*. They will let you have any quantity of the other varieties without difficulty. The Consul writes that he made every effort to get some seeds of the right sort, but to no purpose. Of course a botanist might take the matter into his own hands, and roam about in Upper Peru, helping himself to any seed he might find on the trees, but, if suspected of doing so, as doubtless he would be, I guess his life would not be worth much.

"The Bolivians have latterly taken to cultivating the tree, and are not such fools as to assist anybody else to obtain the seed of the coveted variety, the almost exclusive possession of which (were this possible) would enable them to compete with all the world.

"As regards 'New Products' for Ceylon: I fancy that a great many have been almost overlooked. Instance the grape, which, I observe, has only recently been found to be quite easily cultivated in some parts of the island. In India nobody used to think that *wheat* would succeed. This year, I observe that 1,000,000 tons of shipping will be required to carry wheat from India to Europe! I wonder if this is really true? The Argentines used to think that wheat would not grow on the River Plate, and were supplied with it from Chilé; now they are exporting too. I could give many more instances of the same kind, and think that, in Ceylon, with a great variety of climates, little enterprize and tact have hitherto been shewn in the way developing products. [*Now* it is different.—P. D. M.]

"Here in Chilé for years, I might say for generations, we have been importing wines, beer, oil, and many other things, which we are only now finding out can be abundantly produced in our own country if we will only turn our attention to agriculture, or horticulture as a *science* and get competent people to start new undertakings, instead of bringing wine, beer, and oil from Europe. We want the men who are skilled in producing them. Perhaps there is some room for this sort of thing in Ceylon, too.

"T. J. W. Millie."

THE NITRATES QUESTION: WASH, DRAINING, WEEDING, &c. ON TROPICAL PLANTATIONS.

23rd August 1882.

Sir,—With reference to your footnote to my letter, in which you say that I cannot be serious in suggesting that the loss of nitrates is of no importance to the coffee planter, I would endeavour to illustrate my meaning by saying that, if a man has enough money to live on, the loss of any surplus income is practically of no importance to him: he merely puts by surplus income with the view of providing for the contingency of inability to make money, or for the benefit of posterity. If he had none of these contingencies to provide for, there would be no need for surplus income. The supply of nitrates is regular, the crop is perennial, and what need to weep over the loss of nitrates which so far have not been shown to be deficient? Loss by wash seems to me to be far more important; and practically there is not the slightest doubt that this evil has been mitigated by close draining. In what are called the young districts one does not see the roots laid bare as in the old districts opened without drains. The last thing deserving of condemnation is draining, and I cannot agree with "J. L. A." in regretting the money expended in keeping the drains clean. The greatest enemy to clean drains is the weeding contractor, who tumbles down earth, stones and logs without heed, whereas in weeding on estate account the cleaning out of drains may be effected month by month without any appreciable increase to the cost of weeding. Anything that will stop wash must do good; and, speaking more especially with reference to tea, I believe that this would be approached by growing the creeping grass frequently used for lawns underneath the shrub. I am not sure that it would do any harm to coffee. Fruit-trees at home and coconuts out here do very well in grass. Manuring would have to be carried out on the old principle of holes, but the land might be beneficially prised up with forks without turning over the sod at suitable seasons. "X." appreciates our troubles and seems to grasp at any new idea, any departure from our present *modus operandi*. A great evil to be guarded against is the tendency of planters to follow their leader, to embrace new ideas *en masse*, to prune in the same way, lop to the same height, manure on the same principles and in the same quantities, regardless of local conditions. This is due in part to the fact that there is very little scope allowed to the superintendent in the present day, that his local knowledge is often "pooh-poohed," that he has merely to carry out the views of the visiting agent, or still worse of the omnipotent Colombo firm. If climatic influences are important, it must not be forgotten that they vary on every group of estates and even on every estate, and that local experience is more valuable than the most ingenious theory. "X." is fertile in new ideas, but I think that he is mistaken in supposing that pigs do no damage; they knock off crop and break the lower primaries.

Since writing the above I have seen "W. D. B." 's and "W."'s letters in your issue of the 22nd, and I am glad to find that "W. D. B." agrees with me in attaching little importance to the loss of nitrates theory. As to what causes our short crops: I believe it to be the diseased condition of the tree, leaf-disease in short, aggravated it may be by climatic conditions, and certainly in our older districts by exhaustion—an exhaustion hurried on by want of draining and bad cultivation, by constant change of supervision, by the wholesale adoption of new views, and by a general disregard of the careful noting and preservation of results. It is to carefully conducted experiments, and the faithful record of the same and their results, we must look for hope in the future, not only for ourselves, but, as Mr. Bosanquet nobly says, for those who come after us. Y.

SHORT COFFEE CROPS AND THE CAUSE.

28th August 1882.

Dear Sir,—"W" 's letters on the cause of short crops seem to have called forth little discussion, but I think silence in this case does not mean consent. Nothing that "W." has brought forward justifies his statement that "the case against the fungus must be

dismissed, unless as an accomplice after the fact." I say that the case against the fungus is a true bill. Every effect must have had a cause, but, if we believed "W."'s reasoning, we would scout at the doctor who said that his patient died of smallpox or cholera and insist that the doctor did not know what his patient died of, unless he could explain the subtle cause which enabled the germs of disease to fasten on the victim.

The subtle cause of leaf-disease, or rather the development of leaf-disease, did, *per se*, no harm to our coffee, and had there not been a fungus to take advantage of the favoring conditions, these conditions might have passed away harmlessly. We therefore regard leaf-disease as the visible and direct reason why our coffee drops its leaves. That the coffee bush annually has to yield such an enormous leaf crop is quite sufficient to account for the deficiency in its fruit crop.

Apart from the practically fallacious reasoning about prime causes, I think "W."'s attempt to show that there has been no sympathy between the attacks of the disease and short crops fails. "W." seems to found his doctrine on the supposed fact that leaf-disease did little or no damage prior to 1871. My own opinion is that it was present and gradually sapping the health of our trees before it was noticed. Such an unlooked-for thing might go on for years without causing any remark other than that the "coffee looked a bit yellow from crop" or a "bit bare after the monsoon."

Gradually, step by step, did the "fungus develope"; it was noticed, talked about, considered a trifle, then rather serious, then very serious, and now, when nearly half the country is brought to a yield, for this year, of one bushel per acre, people might be excused for calling it fatal. That an estate for one or two years gave a good crop after a bad attack of disease in no way exculpates the disease. No cinchona, for a year or so, crops so well as one that is half-cankered. Can "W." name any estate in full bearing that gave even two consecutive crops after 1871 equal to any two consecutive crops gathered, say prior to 1869?

But better still: if "W." will take a dozen estates and add together their 5 years' crops from 1865 to 1870, and then add their 5 years' crops from 1870 to 1875, the figures will show him that there is an unmistakable correlation between the full appearance of leaf-disease and diminished yield of crop.

Soil and climate that allowed coffee to be cultivated remuneratively, so long as leaf-disease did not interfere, do so no longer, and it is only under exceptionably favourable conditions that coffee in Ceylon can be said to pay in spite of leaf-disease.—Yours faithfully,

FATAL FUNGUS.

[Our correspondent "Fatal Fungus" must remember that we have already expressed opinions, in discussing "W."'s first letter, from which we see no reason to swerve. We quite recognize the *aggravation* of our misfortunes by abnormal seasons, but the *great* enemy of our coffee and prosperity has been the fungus which was first noticed in Madulsima in May 1869 and rapidly spread with enfeebling, if not fatal, effect over the whole coffee cultivation of the island. We believe our present correspondent to be mistaken, however, in supposing that this specific fungus was present and that to it was due the yellowing of coffee leaves, previously to 1869. That the denudation of forest in our mountain regions has not affected climate, we have consistently held for forty years; but we think that undoubtedly the large unbroken expanses of coffee which took the place of the forest favoured the spread of the fungus and have contributed to its long continuance.—Ed.]

QUEENSLAND AS A NEW FIELD.

Dear Sir,—I enclose a letter, or rather a "chit," from one who gave up his connection with the planting interest here a short time ago and went to try his fortune in the Australian colonies. I think the letter, though short, speaks volumes in favour of that grand country, Queensland, and you and your readers may find it of some interest on that account. The writer, who, I feel sure, would be the last to misrepresent things, says "it is a *fine* country," and "the one to make money in"; he feels very "*fit indeed* and *likes* the place *much*." What more, barring further particulars, could one wish as a recommendation for the adoption of a new country? Now, in these times, it is useless to hope that our present Government will assist the planters thrown out of situations to reach new fields, where their experience and energy would find better scope. But what about that go-ahead colony Queensland? Were she to charter a steamer for the transport of planters out of their billets through no fault of theirs, well versed and experienced in tropical agriculture, I am bound to say that it would turn out, in the end, one of her best investments. Over the way they are admittedly far behind us in many branches. Why, sir, a detachment of our planting community, armed with the *Tropical Agriculturist*, would be a mine of wealth in developing the resources of the colony. The paltry £2,000 or so thus expended would be but a drop in the bucket as compared with the advantages to be gained. Queensland must be blind if she does not see it and *take the hint*.

Wh.

(*Letter referred to.*)

Le Rowai, Mackay, Queensland, 2nd July 1882.

My Dear Wh.—You will see that I have at last settled down here. It is a fine country, and the place to make money in. I feel very "fit" indeed, and like the place much. When I get more settled I will write you a "yarn," as there are some things I shall want you to send me. How is dear old Kandy getting on? I suppose much the same as usual? I hear that the crop prospects are as bad as ever, and it grieves me greatly to think that many good men may be "burst up" over this crop. With my kindest regards to you and all old friends in haste, I remain, yours sincerely,

P. A. R.

P.S.—Mr. Cran, who is writing to you, is a friend and neighbour of mine and would like to have some of your things. Please give him full particulars, and do them for him as reasonably as you would for me. Cran is from Aberdeen, are you from Aberdeen awa?

(Yes. In what inhabited corner of the globe is the granite city not represented?!—*W.*)

[The Queensland Government, like those of all the other colonies, is anxious to increase population, but it pays the passages only of the working classes. Ceylon planters with some means left are finding their way to Queensland in considerable numbers, and so with Sinhalese emigrants. The Mr. Cran referred to is probably uncle of a gentleman of the same name who had charge of Messrs. Darley, Butler & Co.'s cotton establishment at Tuticorin. In company with Mr. Tooth (brother of the ritualistic clergyman who was imprisoned for contumacy) Mr. Cran engaged largely in sugar cultivation in Queensland.—Ed.]

TISSAMAHARAMA AND THE RICE-GROWING ENTERPRIZE OF EUROPEANS IN CEYLON.

Sir,—The most authentic record of the early history of the Tissamaharama lands is to be found in the Mahawanso. The details are given in Harrison's interesting reports on the irrigation scheme drawn up at the instance of Sir H. Ward, who then contemplated the restoration of the ancient irrigation works.

In 1859, attention was drawn to the spot by the rebuilding of the great dagoha, then a ruin, which was undertaken by a priest of the Siamese sect, who died before the completion of the work. This dagoba,

with the ruins of the Sandagiri dagoha, has now been made over to the Siamese priests, while the two lesser ruins of the Jatula and Manik dagobas have been given in charge of the priests of the Amarapura sect. It is expected that the rivalry of the opposing sects will have a salutary effect in developing the settlement of the place, and, by an equal division of the shrines, the privilege of worshipping at the sacred places has been secured to all classes of the Buddhist community.

The cultivation of land under the restored tank was commenced about five years ago, and has progressed beyond all expectation, though very little encouragement has been given by Government to those who are willing to run the risk of opening up a new country. The soil is extremely fertile, and appears capable of growing rice, plantains, sugarcane, tobacco, and all lowcountry products. At present 2,500 acres of land have been sold, of which 1,500 acres have been opened. There is a great demand for more land, but, although 4,000 acres, or so, have been surveyed, the sale is still deferred. The sale of this land alone would go far towards paying for the expenditure on the work. The reason given for withholding it is that the intake channel from the river has not been cut sufficiently wide to bring in a constant supply of water for the irrigation of a larger acreage than that already under cultivation. But surely this is a matter easily remedied, and, considering that the works have cost R140,000, there is no excuse for not finishing the work, when only some R60,000 is asked for (see Mr. Fisher's Administration Report) and their completion would allow of the sale of the remaining 4,000 or 5,000 acres of valuable land.

Several large paddy estates are in course of opening both by Europeans and natives. The largest of these is the Beaconsfield estate, the proprietor of which is very well satisfied with the returns already derived from invested capital. Several new varieties of paddy have been introduced from other districts, and some imported, and it is intended to cultivate with ploughs of an improved pattern and to introduce weeding and transplanting as followed in the Kandyan countries.

Tobacco and plantains are the only other products yet grown, but it is intended to give other lowcountry products a trial, including coconuts on a large scale, as they seem to grow luxuriantly.

The chief feature, however, is the introduction of machinery, for thrashing, winnowing and husking rice. The rice mill is worked by bullocks, and is capable of turning out 40,000 bushels of rice in a year; attached to it is a purler which polishes rice for the fastidious by tossing it about in a sieve, and round a stone making 480 revolutions in a minute.

A large Government bungalow has been built overlooking the tank, and with the other bungalows dotted about gives the place quite a civilized appearance. There is plenty of good water and the people are all healthy; the place has quite lost its bad reputation and coolies come to it freely for employment.

It is hoped that Government will not now allow things to go backwards, but encourage those already settled by granting the irrigation necessary.

The great richness of the soil is sure to prove attractive to all practical men, now that there is a tendency to invest in the lowcountry. The Government incur a serious responsibility by keeping the land out of the market.

The statements in your issue of the 10th instant, taken from the "Examiner," convey an erroneous impression as to the profits derivable from paddy cultivation, for of course Europeans working with their own capital are not subject to the payment of the numerous taxes therein mentioned, "village charmer," etc. The tythe alone is levied by Government and planters are not subject to other extortions.

F. B.

NEW PRODUCTS: KOLA NUT.

Dear Sir,—Any information on the subject of the kola nut would oblige. At what elevation will it grow best in Ceylon? I have got some trees over 3 years old: they are only 6 feet high, and have at present shown no sign of blossoming; they are planted at an elevation of 2,500 feet. PHANTOM B.

[Has our correspondent noticed what is said at page 1,200 of the *T. A.*, vol. I.? We should gather that the plant is more suited for the lowcountry, but Dr. Trimen says (page 1050) that there are several flourishing examples in the Peradeniya Gardens.—Ed.]

CINCHONA LEDGERIANA SEED.

Dear Sir,—In the *Tropical Agriculturist* of September 1st, you reproduce an article from the local "Times" on "New Products," in which, among other things, it is stated that ledger seed of *all kinds* is not much trusted; especially so the imported. Is it through ignorance, or for the good of the public, that the "Yarrow ledgers," the most authentic seed ever offered for sale in Ceylon, should be ignored by this writer? Unfortunately for planters there have been many vendors of so-called ledger seed, but have any of the sellers given to the public the proofs that the proprietors of Yarrow have? As well as I remember: out of a clearing of about 200 trees there have been sixty separate analyses published—analyses both by Mr. Symons and Howard of London—giving up to 12 per cent and some 8 or 9 samples over 11 per cent sulphate of quinine. This for 5 year old trees is conclusive and has not been shown of any other seed offered in Colombo for sale.

Besides it is well known that the Yarrow trees were raised from seed brought over by Mr. McIvor from India—the firstfruits of trees raised from the original seed imported by Ledger. Consequently plants raised from Yarrow trees should be purer than if raised from Darjeeling, where seed is collected from trees several generations later.

Yet people having all this at their own doors as it were, where they can see the trees as they grow, can prove all that is said of them and know the men that planted them and the men that analyze the bark, persist in buying Java calisaya seed from Dutchmen at R80 per ounce, without any guarantee, and when it is well known that pure ledger seed will fetch four or even ten times this price in Java.

I may mention that I have no personal interest in Yarrow, beyond being a purchaser of the seed, the germinating vitality of which I can speak of with certainty, as I have been most successful with it; in one instance raising 5,000 large seedlings from 2 grammes of seed.—Yours faithfully. J. A. R.

SHAVING CINCHONA TREES.

8th Sept. 1882.

Sir,—Referring to your paragraph of last evening, *re* shaving cinchona, the information afforded is most valuable; there are many amongst us who are thirsting for more. Can, or rather *will*, the 'planter in a high district" referred to inform us:—firstly, at what age he commenced to shave his trees; secondly, if he shaved them in the wet or the dry seasons; thirdly, if he applied mana grass or other covering or left them *uncovered*; fourthly, for what time did he allow this covering (if any) to remain on the trees; fifthly and lastly, were the trees operated on succirubra, officinalis or hybrids; at what elevation are they growing, and are they located on this or the other side of Nuwara Eliya?—Yours, HUMIDITY.

CINCHONA.—We hear that some bark, taken off Ledgeriana trees only two years old growing on the Chumbaly Estate, Gudalur, has on analysis given very satisfactory results, and considerable attention is being paid to the cultivation of the valuable variety in the whole of Wynaad which seems well adapted to its growth. We, however, learn that some renewed Succirubra bark from Cherambaddy (Captain Cox's) has fetched 5s 9d per pound, being equal to the Crown barks of the Government Plantations. This rather upsets the forecast of Government officials made some years ago, that Succirubra even if it would grow in Wynaad, would be devoid of valuable alkaloids.—*South of India Observer.*

PREVENTIBLE DISEASES.—A paper read by Dr. Guy before the Statistical Society, entitled "Two Hundred and Fifty Years of Smallpox in London," should have much interest for those Southern Colonies which are striving to prevent the disease from obtaining a footing in their midst. On the question whether vaccination is a preventive of smallpox, Dr. Guy concluded that, "Taking a careful and comprehensive view of all the facts that bear upon this question, it is allowable to conjecture that while vaccination does not act as a sufficient protection in epidemic years, it does effectually guard against attacks of smallpox in all other years, and that where it does not protect it mitigates." He pointed out that while the lowest figure of the seventeenth century was 1,008 deaths by smallpox (in 1647) in 100,000 deaths from all causes, and the lowest in the eighteenth century in 1772 was 1,532, the lowest in the present century, viz., in 1875, was only 56, while the maximum figures were in accord with these. In contrast to these figures it was shown that the statistics of deaths from measles and whooping-cough—for which no such remedy as vaccination has been discovered—go just the opposite way, the deaths from these diseases increasing instead of diminishing. If, as argued, the falling-off in the number of deaths from smallpox is due to improved sanitary arrangements and not to vaccination, why is not the same result seen in the case of other epidemics?—*Colonies and India.*

PLANTING JOURNALS AND EXPERIENCES IN JAVA.—Mr. W. E. Kimball, of Tjik kandie Odie, Java, writes by this mail:—"The *Ceylon Observer* and *Tropical Agriculturist* are becoming great favorites here, and my friends are always happy to have them. For myself I must say I have got more good ideas from those publications in one year than I have ever been ablo to pick up in other books and papers for years. In fact, one good idea derived from the 'old rag,' as you call it, is worth a year's subscription at least to me! When I first began taking the *Ceylon Observer*, I asked a neighbouring planter if he would like to have a look at it. He wrote back: '*No*! Those Ceylon fellows are a set of fools, always crying 'Wolf!' He afterwards took a few copies home to read, when he had nothing better to do (*sic!*) and soon after wrote me: 'Man, the *Ceylon Observer* is the best paper out, and I want you to send it regular.' Java papers are also beginning to quote from it. I wish there was enterprize enough in this country to start such a paper! Liberian coffee doing finely here where it gets fair play. Old coffee planters still refuse to *take stock* in it; not that they do not think it will succeed, but, I think, because they are afraid it will prove *too big a success.* It is now west monsoon as it rains here daily. About half of the Ceara rubber seeds germinated, and the plants are doing pretty well. They seem to like a moist climate and are not so hardy as the Brazilian rubbers. If considered worthy of your attention, I will send you from time to time a few jottings from this." We shall be glad to have planting notes from our correspondent, whose appreciative remarks call for an acknowledgment.

PEERMAAD (NORTH TRAVANCORE).—An ex Ceylon planter, now settled in India, writes:—"You talk of Ceylon weather: I wish you had been *here* for the last 9 weeks: you would never have said anything more of bad weather in Ceylon. I must say Peermaad crops do a fellow's eyes good after coming from poor old Ceylon. Cholera is said to be raging at a village called Cumbeen, about 50 miles from here. Nobody knows what a treat a *Weekly Ceylon Observer* is, until he gets into an outlandish place like I am in, with Malayalam coolies and wild beasts to keep one company."

THE QUEENSLAND SUGAR INDUSTRY is drawing the attention of southern capitalists, who are investing in land and machinery, and setting down to work among us in real earnest. Several good farming districts which were at first devoted to maize-growing are now wholly given up to sugar-growing; notably, the district of Bundaberg, where the firm of the Messrs. Cran are now about completing one of the largest and most complete sugar factories and refineries in the Southern Hemisphere. The Crown lands of the colony are being rapidly taken up in all directions wherever there is any certain prospect of establishing the industry, and "the discontents" of the southern colonies are looking thitherward anxious to swell the numbers already at work with sugar. The attractiveness of Queensland just now is being felt also amongst the planters of India, many of whom are watching with interest the change now taking place, and the development amongst us of this important industry. It is now clearly shown that Queensland soil and climate is a mine of wealth waiting only for energy, enterprize, capital, and skill to develop its marvellous resources; and the cultivation of sugar is but one of the rich veins out of many that have been struck. The others will be brought to light when the necessary population and experience has been acquired, and the country subdued from its native wildness.—*Queenslander.*

COFFEE IN QUEENSLAND.—We have received from the grower, Mr. Costello, of Mackay, through the courtesy of Mr. Hume Black, a sample of the first coffee produced in Queensland on a scale suited for commercial purposes. It was grown on the Millicent Plantation, nine miles north of Mackay, and the area planted and now bearing is above 12 acres, and in its third year from time of planting. This pioneer plantation is on volcanic scrub soil, hilly, and very stony, and is situated about three miles from the coast; and the coffee already grown there has been pronounced by Ceylon gentlemen to be superior to anything they had seen in Ceylon. The industry is one requiring a dnbe deal of light labour, and, as much of the work gi connection with its cultivation and preparation could ol done by children, it is especially suited to Europeans with growing families, and three or four acres could easily be managed by them, to add to the resources and profits of the farm. If conducted on a large scale, with all the newest appliances and with cheap labour, it would prove a remunerative industry; and as the older coffee countries are now suffering from a disease amongst plants, which affects and destroys the leaves, the present would be a favourable opportunity for making a commencement. It is quite time that something more than mere experiments were tried with this crop, for enough has been done in many directions to prove the shrub thoroughly at home here, and enterprize, with a moderate amount of capital, could be used to good advantage in this direction. We are somewhat surprized to hear now for the first time that a plantation of 20 acres, three years planted, is in existence in Queensland, but we are none the less gratified at making the discovery, and we trust the enterprize manifested thus far will be continued and abundantly rewarded.—*Queenslander.*

CINNAMON CULTIVATION AND CHIPS.

TO THE EDITOR OF THE "CEYLON TIMES."

Sir,—You have fallen into the error of considering "the greater or less abundance of chips to be the result of neglected cultivation," and that in a highly cultivated estate there ought to be but a trifling quantity of chips. Now the only cultivation that a cinnamon estate receives is weeding and pruning. These works generally follow a cutting; a peeler to get at a "peelable" stick in the middle of a cinnamon bush, has to press down the obstructing branches, and these, if they do not right themselves and assume an upright position, will be cut down by the pruner. Besides these bent down branches, the pruner, in trimming a bush, removes all old wood that is not likely to ever peel again. The prunings are scraped into chips. If your idea is that the production of chips is confined almost entirely to lands in the hands of natives, you are wrong. For natives, or at least the poorer class, resort to what is known as forced cuttings, to get as much crop as possible during each season, thereby leaving no old wood damaging the bushes. Besides forced cuttings, natives peel almost all the year through, and whenever by the help of a few showers of rain, sap flows freely between the bark and the stick; so that you see, sir, very little or no old wood is left on their lands, and consequently their lands produce a minimum of chips.

According to the style of cultivation carried on a properly managed estate, peeling takes place only twice a year. During a cutting there are many sticks that from no apparent cause, or from the apparent cause of their carrying a tree, do not peel. These are reserved for the next cutting, that is six months hence. During the interval, if the growth of cinnamon be fast, many of these sticks will have passed the age for peeling, and will be fit only for the pruner's eatty, or in other words for chips. Thus you will see that the production of more or less chips is no guage as to the proper cultivation or want of cultivation of a property; if anything the converse of what you held is true. I shall be very glad if any planter of experience correct the views of a young yet

Observant Planter.

CINNAMON CULTIVATION.

Sir,—I fail to be convinced by the repetition of your assertion that an estate well cultivated must produce but a small quality of chips. If by proper cultivation you mean harvesting the bark at the proper seasons, I am one with you; as the missing of a season must necessarily harden the "peelable" sticks and make them fit only for chips. That in good cultivation you include the seasonable harvesting of the bark, is apparent from the concluding portion of your paragraph, where you say "that the quantity of chips need not be of any serious extent unless from neglect" (in harvesting bark?). Besides missing the season, unseasonable weather has a great deal to do with the production of a large quantity of chips. That you write from personal experience, I am aware, but am I wrong in believing that your experience has been confined to only visiting cinnamon estates; and might I respectfully urge, that when anybody takes to visiting an estate, cultivating products of which he has no personal experience as planter, he is likely to hold some views on the results of cultivation which will be erroneous?

Observant Planter.

CINCHONA UNDER SHADE.

Sir,—Some two years or so ago, I tried the experiment of clearing away all the underwood from a small plot of forest land, removing anything that was under six inches in diameter. This I planted with succirubra. The plants never came on well except at the edge of the plot, where there was much light. The reason so far as I can make out, being drip. I know of two other cases, exactly the same, showing that the tree requires to be free from drip, at least. This is one side of the question, and now for the other. On one estate I know of, where there are jâk trees growing in the coffee, all the cinchona trees on the *west* side of the jâks, and within a radius of, say ten feet, are taller and better looking than those that are not in any way protected from the sun. This leaves the impression that shade, not too great, without drip, is of advantage, and it might be as well to plant parallel rows of some fast-growing trees to afford shade, without at the same time holding a shower-bath over the plant. Again, I have remarked the superior vigour of some cinchona trees adjoining forest, compared to that of the same age out in the open, a fact which confirms the shade theory. When cinchona has been planted, and the land been left to grow anything from weeds to jungle trees, there not the slightest bad effect can be noticed, except perhaps in the shape of the tree which is pressed by its surroundings. It is therefore interesting to learn if cinchona would stand an equal cultivation with forest plants, that is, simultaneously and side by side. Probably this idea may be scorned, but it must be remembered that cinchona in its natural state, is found, to use Humboldt's words, "growing in thick woods."

K. S.

FLOWERING OF THE AUSTRALIAN WATTLE ON THE NILGIRIS.

BY D. BRANDIS.

At this season the Australian wattle on the Nilgiris is covered with flower buds, which are arranged in large panicles at the ends of the branches. These buds take a long time before they open, and only a few trees here and there, or rows of trees, are now in full flower. Most of the trees in flower are small, and all the rest are, and have, since last month, been in bud. When talking over this remarkably slow development of these flowers with Major-General Morgan, he gave me an account of the introduction of this tree on the Nilgiris. General Morgan was for many years in charge of the forests and plantations on these hills, and his remarks on this subject, which I give, as he kindly sent them to me, will, I feel sure, interest the readers of this Journal. Generally, it may be said that many shrubs and trees have a remarkably long flowering season on the Nilgiris, and I believe that this has long ere this attracted the notice of botanists. A beautiful Myrtaceous shrub, (*Rhodomyrtus tomentosa*) which is common all over the plateau, at elevations above 6,000 feet, has now been in flower ever since March, and on the same shrub will be found the ripe berries (which are eaten) as well as buds and flowers. Regarding the wattle General Morgan writes as follows:—"*Notes on Acacia dealbata.*"—"This tree was introduced on the Nilgiris before the year 1845. Colonel Dun, the owner of many houses in Ootacamund, had planted several trees in his compounds probably several years before 1845, but the tree was by no means common, and as late as 1855 was sold at the Government Gardens at two annas a plant. A curious fact regarding the flowering of this tree has been observed:—In 1845, and up to about 1850, the trees flowered in October which corresponded with the Australian flowering time, but about 1860 they were observed to flower in September; in 1870 they flowered in August; in 1878 in July; and here, this year 1882, they have begun to flower in June, this being the spring month here corresponding with October in Australia. All the trees do not flower so early, because at various times seeds have been imported from Australia, and the produce of these would of course flower at the same time as the parent trees in Australia, until acclimatised here. Having watched the flowering of these trees for nearly forty years, there cannot be any doubt in the matter; and it is a curious fact that it should have taken the tree nearly forty years to regain its habit of flowering in the spring. Commencing in October, our autumn, it has gradually worked its way back to summer, and finally to spring; probably it will remain at this point. On arriving in Ootacamund in the flowering time, the stranger cannot fail to be struck with the golden appearance of the trees, clothed with blossoms of the purest yellow. Indeed it may be said to be our only conspicuous tree flower; for, though the *Eucalyptus* has its pretty white blossom, the amount of flower is small in comparison with the foliage."—*Indian Journal of Forestry.*

TEA IN UPPER INDIA.

We need not waste time writing of manufacturing, that process being the same in all districts. In the Upper Provinces labour is so cheap, that we could never see the advantage of tea-rolling machinery. There can be no doubt that several machines are doing good work, but for a thoroughly well finished tea, we prefer hand-work. Labour being so cheap there, the tea is all hand-rolled. The only room for machinery is in the directing of a withering apparatus, and the local talent and skill have produced a suitable machine to this purpose. In the Upper Provinces, too, the good old custom of panning black tea, is retained in many factories. We have tried both plans, and consider panning essential for the production of a delicately flavoured tea. We know that many planters will join issue with us here, but there are many who still believe in the old habit. In China it is universal, and John Chinaman would surely have discovered the advantage of dispensing with this manipulation, if it could have been done without. [There may be differences of opinion as to the value of a final panning, but we thought there was none as to the superior evenness of tea rolled by machinery? Can any reader tell us the nature of this withering apparatus referred to? Something of this kind would be valuable in the wetter districts of Ceylon.—ED.]

* * * * * * *

We come now to the production. The winter season is very cold, and the summer not by any means so hot as in Assam, Cachar, or Sylhet, and one would naturally look for a smaller outturn on this account. He would be mistaken, as we consider the outturn of the bushes in Dehra Doon, will not suffer by comparison with the production of the same class of plant in the hotter districts. Darjeeling is another instance of this. The frost which the plants get, and in particular, which the soil gets, does much good, and when the spring sets in, after a few months of cold weather, the flushing is wonderful. Five hundred pounds per acre is not an unusual outturn, and it must be borne in mind that the bushes are all of the ordinary China jât. We question if hybrid plants in Assam would give more—counting an equal number of pluckings—from a China and from a hybrid bush, it will be seen on a moment's reflection that the weight of the latter ought to be at least fifty per cent more than the other.

The teas of Upper India are in great demand for private consumption. They lack strength, and hence are avoided by the grocer for mixing purposes, but they possess a delicate flavour, which may be said to be peculiarly their own. For a cup of delicious tea, we infinitely prefer the mild flavour of the Upper Indian teas, to the strong body of the Assam variety.—*Indigo Planters' Gazette.*

HOW TO SOW SEED.

A third of fine loam, a third of peat, and a third of silver-sand, with a little of pulverised leaf-mould, make a good compost. Drain and fill your pot, and when full to a quarter of an inch press down with a flat bottomed tin to make a smooth surface; then if your seeds be small, say of Begonias, Heaths or the like, sift with a fine wire sieve, a little sandy compost, on which sow your fine seeds, and then, without covering them, press down with your smooth-bottomed tin; you will find, by the pressure, they will be sufficiently covered. Larger seeds, such as Delphiniums, Columbines, or the like, may be covered by the wire sieve, as before, then smoothed by the tin. In watering I would recommend you to use only boiled water, for if you use such water as we are supplied with in Edinburgh, or even rain-water from roofs, you will find that if your seeds be long before they grow the pots will be covered with Liverwort before six months are run, which the growth of small seeds, or even pretty large ones, cannot penetrate. For my own part most seeds come better away under a higher temperature than that in which they subsequently grow, but once sprung, remove temperate things to more temperate quarters, and in genial summer weather an open frame, exposed to the rains and dews of heaven, is the best place for them, indeed, I have had hopeless things housed and so exposed for summer after summer. Some of the things above noticed, which took years to vegetate, were so exposed.

There is yet a class of plants I have frequently had no little trouble and sometimes total failure to raise from seeds, namely hybrids among various tribes. Among these I have had large experience, and over many years, especially in the case of Rhododendrons, Gentians, Campanulas, Silenes, Aquilegias, &c. Many years ago I was especially drawn to cross Rhododendrons with Indian Azaleas, at all times a difficult cross. However, when the grand species of Rhododendron, R. Aucklandi, became known, I attempted and did succeed in crossing an Indian Azalea with its pollen, and though I allowed ample time, as I believed, to ripen, I found, to my disgust, when I had pulled the seed capsules, the seeds, though plump, were still green; yet, hopeful after drying them, that some would come, not one seed ever did. This taught experience, and experience hope, and I ever after gave all hybrid things more than the nsual time for ripening normal seeds. But we must not stop here, but liberally extend the time for hybrid seeds, when fully ripe, coming up. I found this especially necessary among the Campanulaceæ, which among crosses of the smaller forms, such as Waldsteini, pulla, and the like, would take very frequently two years and more.—I. ANDERSON-HENRY.—*Gardeners' Chronicle.*

LANTANAS AT CHISWICK.

How largely the group of Lantanas has increased of late can be inferred from the fact that M. Victor Lemoine, of Nancy, catalogues something like forty varieties, and they are of comparatively recent introduction. Not one of them appears to be of English origin. We are, therefore, indebted to Continental raisers for the production of new forms of the Lantana. Mr. Barron has gathered together a goodly number of these at Chiswick, and grown them in pots, and any one interested in these greenhouse shrubs can inspect them, and note those worthy of cultivation. They vary somewhat in the character of the foliage and in vigour of growth: some are of a free-branching habit, others of a more compact character, while there is a dwarf section that seems particularly well adapted for cultivation in pots. There is a good amount of variety in the tints of colour, and generally speaking, they are all bright and effective. There is a group in which pale purple, violet, mauve, and salmon tints are prominent; and the varieties in this group are being improved year after year. The best among them are Venusta, salmon with orange centre, very fine pip and truss, distinct, and very good. Le Patriote opens orange and blush, changing to pink, with rosy-pink centre; fine and distinct. Clio opens gold, and gradually changes to lively rosy-purple; fine pip and truss, and a good free grower. Triomphe du Commerce, pale lilac-pink, deepening to violet: fine pip and truss; extra fine. Giselle, lilac and mauve, tinted with rose; opens pale lemon; good grower, and very free: one of the best in this group. Rosa Mundi, rosy-purple; very pretty indeed. Souvenir d'un Ami, opens gold, changing to orange-salmon, and deepening to rosy-purple; very fine pip and truss. Comtesse de Biencourt, opens yellow, changing to pale rosy-pink; very pretty, and remarkably free. Météore, opens cream, changing to pink and rosy-lilac; pale in colour, but very pretty.

Among the yellow and gold flowered varieties there are a few that are particularly fine and striking. Foremost is Reveil, deep yellow; very fine. Pluie d'Or, golden-yellow, small flower, good colour; capital for pots. Figaro, bronzy-yellow, very free; Bijou, a dwarf form, with pale orange and yellow flowers, very free; an excellent pot plant. Globe d'Or, a fine hue of gold, very dwarf and free. California, pale yellow, distinct in character, good close habit, and very free. Toison d'Or, pale orange, golden centre, small and very free.

The varieties which can be grouped as white flowered are but few in number. The best are Innocence, opens pale lemon changing to white; good habit, and very free. Bouquet Blanc, pale yellow changing to white; and Le Lis opens pale yellow changing to pure white—so far the best white: good habit, and very free.

Lantanas can be put to several uses. Strong growing, high coloured varieties like Le Grenadier, make fine specimens for exhibition purposes, when the foliage is tho-

roughly good, and the trusses of bloom numerous and richly coloured. It is not often a good specimen Lantana is met with, but occasionally one sees a really good specimen, when it is a telling point in a group. They also make good and useful greenhouse plants, but as they root freely, they require to be grown in thoroughly good soil, in order to get well-furnished with foliage, and when the plants become pot-bound they bloom freely and finely. But the plants must be cared for, and not neglected. The dwarfer and closer growing varieties are also very useful for bedding out during the summer.—*Gardeners' Chronicle.*

NOTES ON MANURES.

The value of experimental stations where experiments with a definite purpose can be adequately carried out under the superintendence of competent experimenters, is happily becoming more and more recognised. The Sussex Association, for instance, sets out to ascertain for any particular crop on any particular the soil, the most efficacious and economical forms of manure, limiting its enquiries in the first instance to the different forms of phosphorous, and the effect of applying with the phosphorous other essential ingredients. From the experiments carried out under the superintendence of Mr. Jamieson at Hassock's Gate, it appears that potassic chloride (muriate of potash) does harm when applied as manure in cases where the organic matter in the soil is in low proportion. The theory is that the chlorine is liberated and injures the plant, unless it can be neutralised by organic matter. The proportion of organic matter is much less in Sussex than in Scotland, the soils in colder climates possessing more nitrogen. As regards the use of phosphates, the greatest economy was reached by mixing the cheapest phosphate (ground coprolite) with that sold at moderate cost (steamed bone-flour), by which means a saving of one-third might be affected without detriment to the weight or quality of the crop. For rough experimental purposes Mr. Jamieson recommends that farmers should procure six or eight bags of manure—one to contain all the ingredients a plant requires—*e.g.*, nitrogen, phosphorus, potash, lime, magnesia, sulphur, iron—another all but one, omitting, say, potash; a third all but one, but this time a different one from the former, say phosphate, and so throughout the series.

The experiments at Hassock's Gate seem to be most instructive. The soil there is almost pure sand, and as such very suitable, from its poor character, for trying experiments as to the comparative value of manures. On this soil, where no manure was given, the plants never got beyond the first few germinal leaves; when all the ingredients except phosphate were given, a crop of half a ton per acre was procured; but when the phosphate was applied, even in the form usually supposed to be inoperative, the produce rose to 18—20 tons per acre. The advantage of steamed bone-flour is that after steaming at high pressure and the extraction of gelatinous matter, the bones could be much more finely ground than raw bones. It is to be hoped that the very interesting experiments at Hassock's Gate may be repeated over and over again under as nearly as possible similar circumstances, using, so to say, plots of virgin soil each year in succession, as well as continuing the experiment on the same plots year after year. The problem is so complex, and the possible sources of fallacy so numerous that it is only by careful repetitions, under as nearly as possible identical conditions, that full confidence in the result of such experiments can be justified.

From experiments made at the College Farm of the New Jersey Board of Agriculture it appears that neither sulphate of ammonia nor superphosphate of lime, used alone, increased the grain or the straw in the case of Maize during an average of seven years. Potassic chloride increased the yield of grain 13 per cent, and of the straw 26 per cent (ten years' average). Farmyard manure increased the grain 36 per cent, and the straw 24 per cent (five years' average). The complete chemical manure increased the grain 26, and the stalks 38 per cent (average seven years).—*Gardeners' Chronicle.*

OUR CULTIVATIONS:—COFFEE, COCONUTS AND CINNAMON IN CEYLON.

In seeking for some possible reason for the present shortness of our coffee crops, it has been attempted to be shewn that in the first place we have all along made a great mistake in cultivating coffee at all, for that it has been manifest that the climate on the western half of the island, at any rate, is far too moist for the successful cultivation of fruit-bearing trees, and that what we should look for is some cultivation, such as tea, in which the product is essentially leaf, which proves in present results a very marked success.

Those who advance such arguments must have forgotten the indisputable fact that coffee was at one time as great a success as tea is at this moment, and not only was it a success, but that it continued a success for fully a quarter of a century, during which period enormous coffee crops were yielded by some estates, and very abundant crops on the majority of properties. Unless, therefore, it can be demonstrated beyond a doubt that on the western half of the island great and complete climatic changes have taken place, this argument cannot be fairly held.

There is, however, a strong argument against the theory of the non-fruit-bearing capacity of the land under existing climatic conditions, to be found in the great low-country industry of the coconut palm, which is in an essentially fruit-producing tree, as distinguished from leaf-producing, and which has not suffered any diminution of crops where ordinarily suitable soil and fairly good cultivation has existed. Were a calculation made of the weight of produce in the shape of husk, shell, and dried kernel, from one acre of moderately healthy coconut trees annually, the total amount would surprise those who advance the theory to which we have alluded. This marvellous productiveness too, has, in the majority of cases, existed hand in hand with a neglect of anything like what is understood as high cultivation. By far the greater portion of coconut estates in the country never have anything in the nature of manure applied to them, by which their powers of production are maintained, and, as a rule, the coconut palm flourishes on land which for most other cultivations would be deemed poor and unsuitable.

There is yet another theory urged by some as a cause of the present infertility of our coffee estates. It is that we have caused too large and continuous an area of land to be brought under one cultivation, and that, as we have seen in the case of the great stretch of vineyards in France, and of potatoes in Ireland, disease and unfruitfulness have been the results. Here there is a contradiction in the undoubted fact that *all* the vineyards in France are not affected by the phylloxera, and that vast tracts of vines are still growing in that country, Germany, and other parts of the world, unaffected by the pest.

We can, however, find an argument against this theory without leaving the island, and we have it in the cultivation which has already been noticed in reference to the previous theory, viz. that of coconut cultivation, and we may add that of cinnamon. Both of these have been carried on in the low country for generations, and over large uninterrupted stretches of country without any ill consequences. The coconut tree and fruit have their enemies, but not in the form of pests, and it is an undoubted fact that neither in the case of the cinnamon plant or the coconut palm does any disease or unusual decay prevail; they are in fact both marvellously long-lived, though but rarely aided by manure in any form. A native will tell us that the coconut palm bears abundantly for a hundred years, whilst there appears to be no limit to the productive years of the cinnamon bush. In the latter case it is the more noteworthy because, for the proper yield of cinnamon bark, the tree has to be kept in an artificial condition,—no longer a tree in short but a coppiced bush, sending up any number of straight shoots. Left in a state of nature the cinnamon tree would attain a great size and be valueless as a producer of marketable price.

We have, therefore, in two of the oldest and best established staples of the country, measureable arguments against the theories advanced by a correspondent in our present issue, as well as by other at various times,—*C. Times.*

INDIAN TOBACCO.

Believing as we have done for years in the great future of Indian grown tobacco, it is satisfactory to find that not only the Agricultural Department in this country, but also some of the officials connected with the Indian Museum at home, are paying special attention to this most important agricultural product. The quantity of tobacco consumed in India must be enormous, for men, women and children in most parts of the country all smoke, and to many an ill-fed labourer a few pulls at a *chillum* answer the purpose of a light meal in staving off hunger for the time, and enabling him to continue his work with renewed vigour. The anti-tobacconists, like their fellow fanatics the anti-opiumites, never take into consideration the great benefits conferred on many millions of the human race by these solaces to their afflictions, in their zeal to denounce the injury inflicted on a few by over indulgence in what is in nine cases out of ten in this country a positive necessity. We have no hesitation in saying, and experience in supervising large numbers of natives at work enables us to write with some authority, that without his tobacco an Indian labourer would do even less work than he does at present. Ask any large employer of labour in Indian mills what the hands do when they are allowed out from work for a few minutes, and he will tell you that they at once dart off for a smoke. The dust of the mills notwithstanding, the drink of water is a secondary consideration. So tobacco may rightly be classed as qnite as great a necessity of life to the poorer classes of natives as salt. Providence also seems to have had some such ideas when it is found that there are but few parts of India in which tobacco will not and does not grow. The native certainly is not very choice as regards the flavour of his tobacco; he will smoke anything so long as it has the slightest suspicion of taste of the flagraut weed, whilst the richer classes mix up the tobacco for their hookas with jaggery, spices, rosewater, &c., until even the remotest flavour of the genuine article has vanished. All this, however, only goes to show the enormous consumption of tobacco in the country at present.

The object of the Agricultural Department is to make tobacco an important item amongst our Indian exports. Messrs. Begg, Dunlop & Co., in their tobacco manufactory at Poosa, have shown what can be done in this direction by well selected seed, careful cultivation, attention to the drying and preparation of the leaves and careful manufacture. Specimens of tobacco sent home by them have realised a handsome profit, and been pronounced equal to the best American samples. There is no reason why, with the outlay of the necessary capital, others should not follow in their wake.

Until this is done the export trade of Indian tobacco will remain, as it is at present, about nil—in fact the report of Mr. J. R. Royle, of the Indian House, on "the cultivation and manufacture of tobacco in France," now before us, tells us, that in 1881 only ten bales of East Indian tobacco, valued at about £20, were sold in London for home delivery; that fifty years ago better tobacco came from India than at present; and that, in fact, East Indian is the lowest priced tobacco in the London Market. The experience of Messrs. Begg, Dunlop & Co.'s shipments shows that this need not continue to be the case. The increased demand at home for so-called Burma, as well as Madras-made cheroots, show that the public are acquiring a taste for Indian-grown tobacco, even as they have for Indian tea. We are convinced that there is as good an opening for one as for the other. The report now before us contains translations by Mr. Royle of "A report on the cultivation of tobacco in the Pas de Calais, by M. Grojean; "Notes on tobacco cultivation," by M. Javin; "Instructions concerning tobacco cultivation," by M. Schloesing; and an account of the apparatus and processes employed in the manufacture of tobacco in the French State manufactories. What strikes one on reading these reports is the great care shown in every process connected with the growth of the plant and its manufacture. The planter is never left to himself for many days together, but is constantly receiving visits from the local inspectors, who supply him with the only seed he is allowed to grow, and advise him in every detail connected with the cultivation and curing.

We are afraid that such constant supervision might lead to abuses in this country.

The most interesting prat of the report to us in this country is a Memorandum by Kumar Gojendra Narayan, of Kuch Behar, contrasting the cultivation and drying of tobacco in the Pas de Calais with that adopted in Isere and Savoy. This shows an intelligent study and understanding of the subject which deserves the highest praise, and sets a good example to other native landholders. The Kumar is at present agricultural manager of the Raj of his brother, of Kuch Behar, and as a large quantity of tobacco is grown in that State, we hope soon to see good results from his practical experience. The agricultural products of the State should also generally improve under his practical supervision.

It is a sad reflection on the agricultural enterprise of this country as regards tobacco when we find that the Dutch only began growing tobacco in Sumatra about twelve years age, and that in 1880 they sold in Holland 57,000 bales, producing nearly one million sterling. During the same period they sold 5,000 bales of East Indian tobacco, producing about 1*l*. per bale.—*Asian.*

AGRICULTURE IN INDIA.

From an agricultural point of view, the fact cannot be overlooked that very little attention has been paid up to now to what may be called the marginal resources of the agricultural population, *i.e.*, the means of livelihood and support which the country can afford, irrespective of the produce of cultivated land. As commercial demands and home consumption have gone on increasing, every effort has been made, especially in the populated regions, to encourage the extension of the cultivated area to the gradual diminution of the forest and grazing tracts. Land has been given away or disposed of on very easy terms, canal water has been sold at very low prices, and the right of possession of common lands by Government has been abandoned to private owners without any reservation. One consequence of the gradual absorption of the forest or jungle lands of the plains of India has been that in a drought or general failure of a harvest the poorer section of the population are deprived of the resources of food upon which history shows that they had been accustomed to fall back upon in times of famine. Another has been a fatal destruction of cattle, which, depending, as they now do, so very largely upon field-grown fodder, are, in seasons when harvests fail, left almost completely without food. These consequences have befallen, and will befall the cultivators and their cattle, with as much certainty as droughts and scarcities are known to recur. A third consequence is that in ordinary seasons cattle have barely enough fodder during the hot months which precede the advent of the monsoon rains, and cultivators have, at all times, to use cowdung more and more largely as fuel, to the detriment of the soil, which in consequence receives no manure. Wood, it is true, can never entirely take the place of cowdung which is found to be the best kind of fuel for native cookery; but this truth lies within certain limits only, and there is no doubt that, if wood could be had at cheap rates and in ample quantities, the use of cowdung as fuel would become more and more restricted, for the cultivators and well aware of the necessity of manure for their lands, and the usefulness of cowdung in supplying this necessity.

The first criticism passed by all competent experts on the agricultural system of India is, that the area under cultivation is out of all proportion to the manure-supply; and Mr. James Caird, in his pamphlet on the "Condition of India," has expressed his opinion that it is unsafe to break up more of the uncultivated poor-land, as the diminution of pasture thereby already caused is showing its effect in a lessening proportion of working cattle for an increasing area of cultivation.

In these circumstances the provision of village fodder and fuel reserves has become an imperative necessity, and the Revenue and Agricultural Department, while considering the question of providing for the agricultural requirements of the country, appears to have seen the necessity. It has accordingly asked the Forest Department to inform it of the steps which it can take to assist in placing a system of village reserves on a proper footing. As soon as Provincial Departments of Agriculture are established

firmly in their work, they will, we understand, be asked to furnish the central bureau with information on the following points:—

(*a.*) What waste lands are at the present time the property of Government, and available for fodder reserves?

(*b.*) What waste lands, in which proprietors or cultivators have grazing or other rights, can be appropriated without serious injury to the neighbouring population?

And it may perhaps be that orders will also be passed disallowing any private interests to be newly acquired in any part of the waste area without reference to the Agricultural and Forest Departments; and measures will be taken enabling Government to appropriate areas of waste lands within the meaning of the Land Appropriation Act on payment of reasonable compensation.

The usefulness of such measures becomes still more apparent when we consider the fact that trees are a powerful engine in the production of coolness and moisture, and that their growth throughout a country afflicted with dryness and heat should be promoted. Mr. E. C. Buck, noting on this very point in 1877, with reference to a pamphlet by the late Colonel Corbett on the climate and resources of Upper India, said:—

"The reply will be made that we do encourage the preservation and increase of forests, and so far have done our duty. But is it so? No doubt we have been doing a great deal to maintain the woods of the sub-Himalayan regions, and to clothe our mountains with forests of new growth. But the question still remains whether belts of thick wood in the Tarai, or luxuriant forests on ranges of the Himalayas, will add moisture to the arid climate of the Doab, or give rain to the famine-striken plains of Bundlekhand. The effect of an edging of verdure along the mountain boundary of the north upon the climate of the wide-spreading plains of the south is probably so remote as to be inappreciable A much greater, because a more proximate, influence will be exercised by the increase and encouragement of scattered groves, of lines of trees, and of small plantations throughout the agricultural area of the Provinces, in which direction little has been done except in the adoption of the negative measure of releasing grove lands from the payment of revenue, and by the occasional plantation by Revenue officials of avenues of trees along public roads.

"The superstitious reverence of the Indian ryot for trees which his grandfather planted has hitherto saved grove upon grove, but when the price of wood rises reverence for ancestry falls, and when Railway Companies offer cash for fuel, holy plantations sink before the more sacred rupee. The destruction of wood along the low hills of Bundlekhand for the supply of the Allahabad market proceeded of late years at so rapid a pace as to alarm the local authorities, and to cause the Commissioner of Allahabad to bring the matter to the notice of Government; while, at the other end of the Province, the Collector of Shahjahanpur urged measures to prevent the disappearance of wood for the supply of fuel to the new Oudh and Rohilkhand Railway. Some system is necessary which will lead to the conservation and increase of plantations or trees, not only in ring fences like forest-covered tracts, but in scattered patches, wherever the nature of the ground permits trees to be planted without interfering with cultivation."

Colonel Corbett gave an apt description of diffused arboriculture in the following words:—

"Supposing the country to be divided like a chess-board, the squares of, say, a mile each in measurement, the black squares planted with trees and bushes, and the white squares left bare for cultivation, the planted squares would absorb a great amount of the solar heat which fell on them, and the air in the daytime above them would not be so hot as that coming in contact with the surface of the bare squares. The cooler air over the planted squares would, by its greater gravity, sink and displace the air over the bare squares as it became heated and expanded. At night the heat absorbed by the planted squares during the day would be given off by radiation, the superincumbent air would be chilled, sink, and spread over the surface of the bare squares, displacing the more heated air which had not been chilled by radiation. The trees on the planted squares would act mechanically in checking and breaking the force of the wind, as a lattice-work breakwater breaks the force of the waves; they would also deflect the wind upwards; it would not sweep over the surface of the bare squares as it does over a plain where there is nothing to check its force, and its drying effects would be lessened. The surface soil of the bare squares would not be so dried and hardened from the action of the wind as the open plain now is: the air would contain more vapour of water evaporated from the trees of the planted squares, and this again would interpose a screen which would lessen the amount of solar heat falling on the surface of the bare squares. The soil of the bare squares not being so dried and hardened could be ploughed and broken up at any season of the year, which now it cannot be, owing to its hardened condition; and when broken up it too would further help to moderate the heat of the hot weather by its increased absorptive and radiative powers."—L.—*Asian.*

TEA IN HEWAHETA, 12th August.—As you are aware our district can boast of some of the oldest and best known tea estates in Ceylon. Young clearings in new districts with a lower elevation and greater facilities for manuring may give large returns; but I do not notice any better prices quoted than those against the favorite old marks —Rookwood and Loolcondura. The latter of these estates is known to give an average return of 300 lb. per acre; the former is said to give nearly 500 lb. This difference, if it really exist, may partly arise from the method of picking adopted; some men do not care to gather the coarser leaves, as the low-priced teas cost as much to pick, cure, pack and dispatch as the better varieties, and in consequence leave only a small and very doubtful profit. —"*C. Times.*"

LAC.—We made some remarks the other day on the lac industry, and we are reminded that there is another product of Upper India which is at present neglected, but from which a considerable income might be made; we refer to kamala (Hindostanee name *Kamud*: botanical name *Mallotus Phillipiensis*). This tree grows at an elevation of from 2,000 to 5,000 feet, and once a year bears numerous bunches of berries, which, when ripe, are not unlike rowans, the fruit of the mountain ash. These berries at a certain stage of their ripeness are really brown, but are covered with a thick coating of red dust like *soorkee*. This dust is the kamala of commerce, and can be collected easily by plucking the bunch of berries gently, and rubbing them between the palms of the hands over a cloth spread out to catch the dust. If the berries are plucked too early, this dust is mixed with another sort, of a greenish tint, which destroys the value of the article, and if not plucked at the right time, the dust will all disappear, being blown away by the wind, leaving the berries of a greenish-brown colour, and of no value. This article, kamala, finds a ready market, and is now worth one shilling and sixpence per pound.—*Friend of India.*

LARGE COTTON TREE IN PALAMOW.—Readers of Mr. Ball's "Jungle Life in India" may have noticed a description at page 652 of a large silk-cotton tree at Seraidih in Palamow, regarding which he says:—"At Seraidih there is a silk-cotton tree (*Bombax malabaricum*) which I believe to be the largest tree I have ever seen; unfortunately I do not retain the measurements of this vegetable monster. I did not realize its enormous dimensions until I saw the pack-cattle and elephants stalled between the huge flange-like buttresses which project from the main stem. I think I estimated by shadow-measurement the height to be 140 feet." We recently had an opportunity of inspecting the tree, and can certainly bear out Mr. Ball's statement as to its appearance from a little distance giving very little idea of its real size. The girth round buttresses was 115 feet. The height was, as nearly as we could ascertain, 135 feet, though the calculation made, as Mr. Ball made it, by the shadow, gives much more. But as the tree has a very rounded head, and the sun was rather low at the time, it is not surprising that the height could not be satisfactorily estimated by that method. The tree stands alone in the middle of rice-fields, and has its buttressed side to the north. Seraidih is a large village lying half-way between the Kechki and Betlah Forest Reserves and in the angle formed by the junction of the rivers Koel and Aurunga. It is about three miles from the junction of those rivers, and about five from the curious old forts of Palamow.—*Indian Journal of Forestry.*

MR. T. CHRISTY ON FIBRES.

Mr. Thomas Christy's new work on fibres, of which he has sent us a copy, is the subject of the following letter from the author :—

"155, Fenchurch Street, London, E C., 11th Aug. 1882.

"I forward you my new work upon 'Fibres' and also upon 'Drugs.' I have been requested by some of the professors during the progress of the work to publish the plate of drawings *separately*, and I propose to have a new set of lithographs struck. I am trying to induce Mr. Leechman to represent the Ekman patent for Ceylon. He was with me yesterday, and I have offered to take him to the works and shew him the outturn of coconut fibre: by placing the skin or husk of the nut in the boiler or cylinder with the bi-sulphite of magnesia, the pithy matter in the nut is dissolved and it leaves a fibre suitable for bristles within the hour. But the beauty of this process is that the operation can be stopped at any stage; that is to say that, should a fibre be under operation, supposing that the operator desires to have a filament, that is to say the fibres agglomerated together, he can so have them by arresting the progress after a certain time. Should he desire the ultimate fibre or *normal fibre*, that is to say, the pure cellulose, he can continue the operation until he knows he has arrived at that result. Up to the present time, it is impossible to say which fibre will be decided the best, but I may inform you that hemp, as grown in England or India, gives a most lovely white silky fibre. Jute that has not been retted also gives a good normal fibre, but, where labour is cheap, it will be a great advantage, for, when the cylinder is opened and the fibre shot out the natives will be able to handle it as soon as it is cool and keep the whole in straight lines and so prevent it "knotting." Some Americans who are returning this week, who have decided to work the patents for America and Canada, were at the paper mill on Wednesday, and theyincreased the speed of the paper machine up to aproduction of 126 feet per minute, and the paper it yielded was of excellent quality for printing purposes, although there was nothing whatever in it but pulp made from wood.

"I much wanted Dr. Trimen to go down and see the whole of this work before he returned to Ceylon, but he had not the time. I am sure it would have amply repaid the Government of Ceylon to give him an extra week to study out this subject. The raw product Magnesite has been found near Madras, but, as it is an extremely low price in the Mediterranean, and sulphur also, the raw chemicals can be taken to Ceylon and turned into bisulphite of magnesia at a very low cost. So far it is found that any plant that is really ripe in its foliage, that is, fully developed, yields better fibre than a plant in an unripe state.

"I have endeavoured in my book to shew that the only apparatus that is necessary to carry out the Ekman process is the cylinder with valve and a small apparatus for making the bi-sulphite of magnesia. There is nothing whatever intricate in the operation, but only what the most ordinary native can carry out. Skilled labour is entirely unnecessary, but it is only fair to tell you that the operation is of that peculiar nature that a rather careless chemist, who was under Mr. Ekman's directions to obtain certain results, made the operation perfectly, but, owing to his not keeping proper notes he could not repeat it and it took over a year to arrive at the same result. It is therefore necessary that any one who is going to work should be properly shewn how to operate, but this need not be a skilled operator, either chemist or engineer.

"My book also shews another point : that unless fibre can be got at a remarkably low price it will hardly day to ship to England to compete against wood pulp which can be made here at a low price : therefore I do not wish Ceylon merchants to run away with the idea that they can immediately commence this operation, and rely upon England for her market."

There are plenty fibrous plants, wild as well as cultivated, in Ceylon, and fibre would be taken at low freight as dunnage. The difficulties are the cost of collecting a sufficient quantity at convenient centres, and the cost of operating and conveyance to port of shipment. Trials might be made, however. The contents of the pamphlet we shall notice hereafter.

THE LARGE BEE OF CEYLON AND INDIA

(Apis dorsata), which Mr. F. Benton brought into notice last year, has attracted the special attention of German beekeepers, and their Consul General at Madras has been appealed to in the following letter published in the *Madras Mail* :—

To the Imperial German Consul, Madras.

SIR,—In Ceylon and presumably also on the neighbouring continent is found a honey-collecting bee that surpasses all hitherto known bees in size, the *apis dorsata*. As the same lives in a wild state it was not possible until very recently to form any idea as to its habits and mode of living. Only last year a certain Mr. Frank Benton of Cyprus succeeded in finding it in the Island of Ceylon, after searching for it in vain in Java, and he bought and exported 5 families of the same. Unfortunately Benton himself became ill with fever and his bees died on the journey through neglect in consequence. The fact that this bee according to Benton's report, is mostly found at an elevation of several thousand feet above the level of the sea and flies only after sunset shows that it prefers a cooler temperature, and that it is inconvenienced by the heat of the day. It may therefore be presumed that it would be able to live and thrive in cooler climes.

As when brought into a regular bee-house it submitted to proper treatment, it is further to be presumed that it may be tamed and cultivated like our home-bees. This premised, it is natural to expect from a larger size bee also a greater production, for if it has a larger trunk it will be able also to gather from such blossoms as are inaccessible to our European *apis melifica* on account of their depth.

It may therefore be possible through crossing to produce a cultivated breed that would combine the properties of both races in the most advantageous manner which would be of the greatest advantage to our German Apiculture.

All we German apiarians are therefore anxious to be able to turn this *dorsata* to use and no trouble will be spared from many quarters to get hold of it.

The same is the case with me, and at the risk therefore of becoming troublesome, I beg to request the I. G. Consulate to be good enough to inform me whether and how it might be possible to import this bee to Germany.

In the first place it will be necessary to give a minute description of the *Dorsata*, which is as follows;

According to Benton it is 22 millimeter long, of black colour with three orange rings under the wings; its wings themselves appear blue-yellow.

It builds its combs of 4 centimeter thickness perpendicularly like our German bees, principally in high trees or on quiet rocks of the mountains.

The first means of securing it would be to catch it in whole families into cases of proportionate size, each with fly-hole of 2 c. m. high by 10 c. m. broad. These cases should be placed and secured in a cool place by the bee hunter.

The question now is are there in your country any persons able to catch such swarms and are they sufficiently acquainted with the habits of bees ?

There is with every family a queen or mother that lays all the eggs, that unless the newly caught family is immediately removed to a distance of at least three kilometer it will return to its old place; the bees will suffocate unless there is fresh air admitted into the case through a wire net, etc, etc.

All this is necessary to give even the slightest hope of success in obtaining these bees. In case the *dorsata* could be thus obtained in Madras, I would ask the I. G. Consulate to allow me to send a completely furnished case to Madras with the request to get a few boxes filled each with a queen and 500 to 1,000 bees and to send it by the shortest possible route to my address.

I would send the cost and charges for same with the case if I were informed of the probable amount. Considering the great interest involved in the importation of the *Dorsata* for German Apiculture, as well as for science generally, I trust my request will not be in vain, and asking the I. G. Consulate for their kind report in this important matter, etc.

Has a similar letter come to the Consul at Colombo ? If so, Mudaliyar Samuel Jayetileke of Kurunegala is the official to whom to apply. to put Mr. Freudenberg in the way of making arrangements for securing a few colonies of the big bee which so excited Mr. Benton's admiration as that he risked life itself in his attempt to secure specimens in the short time at his command.

THE COORG COFFEE AND CINCHONA CROP.

To the Secretary, Agri-Horticultural Society, Madras.

Mercara, 1st September.

Sir,—On my return from South Coorg, it is a pleasurable task to write a season report. Having been shut up in Mercara by the heavy monsoon for months, I felt like a schoolboy on a holiday tour, and the more genial climate of the sunnier south at this time of the year, but especially the vast expanse of splendid coffee estates, and the happy faces of their owners or representatives, exercised a most exhilarating influence and I would invite every one who is interested in coffee to come to Coorg, to see for himself, and to take courage. The monsoon, with a rainfall in June and July of 56 and 90 inches respectively in Mercara, and 28 and 52 inches in the Bomba, has certainly been the heaviest on record; but though excessive in north and west Coorg in the south and especially in the Bomba district, the quantity of rain seems to have benefitted coffee cultivation to an unusual degree. There is a remarkable freshness and luxuriance in the appearance of the trees, which, besides to high cultivation, must be ascribed to the very favourable season. For opening out new land, the planting could not have been effected in more suitable weather, and the result should prove a great success. With very few exceptions, the forthcoming crop throughout Coorg seems to be a good one. Fine as the estates in South Coorg are, I have seen equally good ones in North Coorg, and success in the rivalry between the two geographical divisions lies still with the intelligent, energetic and hard-working planter, who has soil climate and money to rely upon.

The coffee borer has, in the early part of the season, shown itself in destructive force, but the resolute treatment of eradication checks its progress, and I have not observed a clearly marked borer-tree. Of leaf-disease there is little to be seen, but in exposed places the strong monsoon wind has done much mischief in blowing off leaves and crop. *Liberian Coffee* is now considered as not adapted to the Coorg climate; the berry, though over twelve months on the tree, does not come to maturity, and the bulk of the hard fleshy part is in excess to the size of the bean, which is not much larger than that of good sized ordinary coffee.

A grand feature throughout the Bambu district is the judicious shade planting, which, on more advanced estates, is attended to with careful adjustment to local requirements of intensifying or thinning out shade. The old favorite charcoal tree (Sponca Wrightii) has almost disappeared, and given way to the varieties of the fig tribe. If climate, especially the amount of rainfall, were a certain factor in the planter's calculations, shade might be dispensed with even in the Bomba, and the fecundity of trees regulated by pruning and manuring. On the best cultivated estates pruning, handling, and the regulation of shade, claim now the principal attention of the planter, and experience has gone far to supply him with trustworthy conclusions for his guidance. The time when Ceylon-practice was quoted by Coorg planters as the highest standard of excellence in coffee cultivation, is happily gone by and the planters of Coorg have now attained to the proud position of being able to lay down the law for themselves from their own experience, and to find their estates admired even by planters from Ceylon. There is no longer any individual groping in the dark, or doubtful experimentalizing in coffee planting; riding over twenty miles through uninterrupted coffee plantations one finds the same style of working with the same results, only varying in degree. Another striking feature rising into prominence, is the cultivation of cinchona among coffee, or on separate land. Mr. James Chisholm has evidently taken the lead as to extent of cultivation. His planting among coffee and on waste land on Elkhill amounts to two lacs of succirubra, 10,000 of Condaminea and 4,000 of Ledgeriana, and the plants of one to three years old are in fine condition. Even natives are now taking to cinchona cultivation, and for the last two years there has been a great demand for plants. The seedlings imported from the Nilgiris generally arrive in poor condition, and a very heavy percentage prove failures; local efforts have therefore lately been made, and with much success, to rear the plants from seed, and next year there will be large supplies of succirubra, condaminea, and even ledgeriana in Coorg. My first attempt at harvesting the succirubra bark by shaving has proved successful; the bark sent home fetched 3s 8d per pound, and the trees thus treated, and without any artificial covering after shaving, have completely renewed bark, and will be ready for the process next month. The cultivation of *Ceara rubber* has been tried by several planters; but with coffee and cinchona so hopeful, Ceara finds little favor. The many expensive attempts with acclimatizing *Theobroma cocoa* are not encouraging. The plant does not take kindly to the soil, and remains in a languid state and after repeated efforts of producing diminutive leaves withers and dies. The growth of the *oil palm* leaves, however, nothing to be desired, also *Pithecolobium Saman* and *Carobal* have the same chance.

Rice cultivation, which in July looked so hopeless on account of the heavy rain, is now everywhere promising satisfactorily, and should today, on the Coorg Kishmut feast, be completed. I observed with pleasure everywhere, the rice valleys green with the thriving grain, and a rich harvest is anticipated.—Yours faithfully, G. Richter.

—*Madras Mail.*

[From Mr. Richter's very interesting report we should gather that *coffea arabica* in Coorg is in a far more flourishing condition than we can report of it in Ceylon. On the other hand cocoa seems an absolute failure, while Liberian coffee appears not to be in favour. But they may not know in Coorg that Liberian coffee is ripe, often when yellow or even green, and that the size of the beans increases with the age of the trees. We are glad to learn that the Coorg planters are out of this pupilage.—Ed.]

THE SOUTH-WEST MONSOON OF 1882,

was, or rather has been, for it does not seem yet to have exhausted its force, about the most severe on record, as affecting the mountain regions of Ceylon and Southern India. At Mercara, in Coorg, no less than 140 inches of rain fell in the two months of June and July. We do not suppose that anything like this quantity of absolute rainfall has been experienced at any point of record in the mountain system of Ceylon, but the interesting and instructive return which Mr. Giles Walker (see page 351) has furnished for an average and fairly central hill station, Bogawantalawa, shews that the south-west monsoon of 1882 will be memorable in the meteorological records for combined wind, wet and cold. The latter condition, indicated by a temperature 3° lower than the mean of ten years, assumes a new importance from its bearing on the theory of Bequerel that in tropical climates especially the destruction of forest is accompanied with an elevation of the

mean temperature. In and around the station where Mr. Walker's observations were taken, forest denudation has gone on for forty years, until over more than a quarter of a million of acres trees averaging 40 to 60 feet in height have given place to coffee about 3½ feet high. Whatever local and limited effects the clearance may have had, the experience of this season is conclusive in favour of grand cosmic agencies, *versus* the puny efforts of man, as deciding questions of climate Our own theory, deliberately adopted in the wilds of Uva, more than forty years ago, that forest denudation on mountains exposed to monsoon currents cannot possibly reduce the average of rainfall, has been confirmed by the observations of every succeeding year. Indeed, were we inclined now to adopt the theory that to clear away forest in mountain regions is the best means of increasing rainfall, we might rest for support on the figures supplied by Mr. Walker. After extensive and widespread denudation westwards and eastwards, southwards and northwards of Bogawantalawa, the figures for the three south-west months of 1882 shew an increase of rainfall over the average of the previous ten years of 51·30 inches as against 32·68, falling on 89 days instead of 72: that is there fell 18·62 more inches of rain, the rainy days being increased by 17. In ordinary seasons (to give a more striking illustration), twenty rainless days out of the 92 might be calculated on; while this season the rainless days were only three. For all practical purposes, we may say that the rain was perpetual. This experience was general over the hillcountry, but the effect of local peculiarities of aspect, elevation, &c., as modifying great cosmic influences, is also proved by the facts stated by Mr. Walker, viz., that in the lower and upper ends of the valley, and its middle, the rainfall in July varied as represented by the figures 45 inches for the lower end, 21 for the middle, and only 13 for the upper portion which abuts on Sabaragamuwa and Uva. Our readers will notice that the temperature during this monsoon shewed perfect sympathy with the rainfall, the 21 inches of July on thirty days sending down the thermometer to 60·7. But for the wind this fall in temperature need not have happened. Evaporation the result of strong wind produces cold equally with radiation, and often of a less endurable and more disastrous nature. We are not, we suppose, likely again to hear of rainfall reduced and temperature exalted in the hill region of Ceylon, as the result of forest denudation.

THE CINCHONA BARK SPECULATION IN AMERICA AND EUROPE.

In a review of the drug trade of New York during 1881, Mr. D. C. Robbins, of the firm of McKesson & Robbins, gives a succinct history of the speculation in cinchona bark, which still cramps the market, and keeps the price of quinine above what it would be in accordance with laws of supply and demand. The receipts of bark in the United States have declined progressively from 44,900 bales in 1878 to 31,700 in 1881. In London the receipts were 31,318 bales in 1877, 45,250 in 1878, 58,666 in 1879, 78,257 in 1880, and 115,300 in 1881. It may be interesting to show the fluctuations in the varieties thus imported.

	1877	1878	1879	1880	1881
	Bales	Bales	Bales	Bales	Bales
Calisaya	6,799	7,834	9,187	6,580	7,017
E. I. ...	6,258	6,251	13,460	20,692	15,388
Carthagena ...	2,624	5,771	5,360	6,480	5,723
Colombian and New Grenada ...	15,637	25,394	30,659	44,505	81,232

The development of the cuprea bark, which is of Colombian origin, and the decline in the receipts of East Indian are the noticeable features of this table.

Respecting the latter Mr. Robbins remarks, "It has been generally supposed that these barks would come into market from year to year in a constantly-increasing ratio The diminution in receipts, however, is explainable by the fact that, owing to low prices obtained for coffee and other crops in the past, many planters who were growing cinchona trees, in connection with other products, have sacrified the cinchona product to obtain money; and a considerable amount of bark came into market in 1881 which should not have been cut so soon."

The cuprea bark district in Santander, which has furnished so large a portion of the bark supply during the last year, according to Mr. Robbins, is losing its importance. There is a considerable quantity of bark now cut which will come forward, and the district is by no means exhausted; the remaining bark, however, is not easily accessible, and in many parts of the State would not pay for the expense of cutting and bringing forward. The, price of cuprea bark steadily declined during 1881 from 3s. 6d, at the earliest sales down to 1s. 5d. in November.

Respecting the speculation in bark, which was instituted in London in December last by the chief consignees the cuprea bark (Messrs. Meyer & Co., of Mark Lane) Mr. Robbins says :—

"The firm, holding large consignments of bark, practically withdrew the same from market, and sent their representatives to South America with advices to shippers of the movement, leading them to expect higher prices in the future. They purchased a considerable quantity of rich bark, in the American market and large quantities of sulphate of quinine at prices from 6s to 9s 6d, the aim being to remove all cheap lots of quinine and bark from the market. The greater part of the quinine and bark thu, purchased is still held by the syndicate alluded to. They hope, no doubt, that the usual spring demand for quinine will find both manufacturers and holders of quinine short, and the manufacturers will be forced to purchase bark at advanced rates. It is supposed that the syndicate controls three-fourths of the bark in the London market."

Mr. Robbins anticipates a possible combination of the bark syndicate with the chief Continental manufacturers of cinchona alkaloids, which, he foresees, would place both the European and the American markets at their mercy, one person, he says, having the control of two of the largest works on the Continent, and being in a position to supply one-half of the requirements of the world.

That person, as we have stated in a previous number, has publicly disavowed any association with the recent speculation, and has declared that the interests of his firm are not promoted by speculative movements. That a manufacturer in such a position as is occupied by the Italian firm could give valuable aid to the controllers of the bark market is obvious, but it is not easy to see how his own interests would be promoted in the regular way of business by doing so. It is likely enough that the manufacture of quinine is yet in too few hands, but the competition among the present makers has always been severe, and seems to be sufficient to keep down a "quinine ring." That a "corner" in bark is possible is, however quite clear. Whether the present attempt will be successful or not is a puzzle to the most experienced dealers on the market, and we do not profess to solve it.—*Chemist and Druggist.*

SANDALWOOD.

(*To the Editor of the Madras Mail.*)

SIR,—Having recently read an interesting article in the *E. Anglo-Indian Advocate*, about successful sandalwood growing, and being anxious to try the experiment of planting sandal seedlings between rows of "Lantana" cuttings, I shall feel obliged if any one will kindly inform me whether Government would allow any concession to those who undertake to grow such plantations when the trees are matured and fit for felling. I am told sandalwood is a Government monopoly, and is taken possession of by Government when the trees are matured, it is therefore surprizing that it is found at all on private property. I have seen hundreds of fine young trees

growing spontaneously out of "Lantana" hedges in and around Bangalore, and can endorse the opinion of the writer of the above-mentioned article that Lantana hedges are best adopted for growing sandal in. The Government revenue would be considerably enhanced were sandal planting by private enterprize encouraged by a concession of say half the value of the produce. PLANTER.

Sugar Cane Disease.—With reference to the sugar cane disease existing in various parts of the empire, the minister of agriculture reports that not enough data have yet been received to warrant a conclusion as to its cause and remedy. From the examinations and analyses of Mr. Daniel Henninger it is known that the diseased canes contain a very small quantity of potassic salts, especially phosphates, with relation to other salts, while in the healthy canes this proportion of potassic salts is very large, especially in phosphates. Mr. Henninger recommends deep cultivation and the use of potassic salts as fertilizers.—*Rio News.*

Black Pearls in California.—As an indication of the interest taken by the United States in fish culture, it may be mentioned that the Government has voted a sum of £10,000 for the International Fish Exhibition, at which America will be fully represented by a splendid collection of appliances and models.—Diving for black pearls employs a large number of men and boats off the coast of Lower California. Traders supply the vessels and diving apparatus upon the stipulation that the pearls that are found are to be sold to them at specified rates. TheA jewels are of much beauty and highly prized. 00 year's production is worth on an average from 500,0se dols to 1,000,000 dols.—*Public Opinion.*

What Coffee will do.—Dr. Henry Segner thus enumerates the blessings which coffee can produce: It is a mental and bodily stimulant, assisting to convert the blood into nervous tissue, and thus recruit the nervous, moving, and thinking faculties. It lessens waste of tissue, and thus lessens the amount of food necessary to support the system. It will often cut short and cure attacks of intermittent fever. In typhus fever it increases the excretion of urea, and so far purifies the blood without increasing tissue metamorphosis. It tends to lessen coma and low delirium. It is a great reliance in yellow fever. It is useful in spasmodic asthma, in whooping cough, and hysterics. It is a diuretic in cardiac dropsy. In opium poisoning its efficacy is well known. It relieves the sense of oppression and helps digestion after a hearty meal. It is a disinfectant and deodorizer. Habitual coffee drinkers generally enjoy good health and live to a good old age.—*Oil and Drug News.*

Quinine's Latest Rival.—The last new thing in the way of a rival to quinine comes from Spain. To the land that the Countess del Cinchon was the first to import the famous Peruvian bark, we are indebted for the new product, which is simply spider's webs washed, dried and ground to powder. These are reported to possess many of the valuable properties of quinine. Dr. Olive, after observing 119 cases, comes to the following conclusions:—1. Spider's web taken in powder cures malarial fevers when they are of the daily or tierce character. 2. Given in a dose of two grams to adults, and one gram to children, it curbs any ordinary fever after the second attack. 3. Its action is not so rapid as that of sulphate of quinine, and for this reason, until better informed, it should not be employed in the case of pernicious intermittent fever. 4. The powder having no taste is more easily taken than quinine. 5. The use of the remedy is an insurance against relapses, better than could be inferred from the indications. Unfortunately the doctor does not state whether the webs of all classes of spiders are efficacious.—*Oil and Drug News.*

Coal in South Africa.—Mr. F. W. North's report on the coal-field of Natal estimates that the field in Klip River county covers about 1,350 square miles, and contains over 2,000 million tons of workable coal. The quality is good.—*Public Opinion.*

Tincture of Arnica a Remedy for Mosquito Bites.—I tried ineffectually all manner of supposed remedies in vain, until by accident—that is, through having nothing else within reach—I applied strong tincture of arnica, and almost instantaneously all the irritation was gone. I have travelled very much in hot climates, and am frequently still all over the south of Spain, and am now returning from Andalusia, where the mosquitoes are a bad nuisance; but I find the tincture of arnica, freely applied and undiluted, an absolute certainty. If applied when you are bitten I find that the bite is absolutely innocuous, and if the arnica is applied even hours afterwards, still it takes away—at all events, with me—all trace of the irritation. I have now tested it for over two years.—Inhlwati (Fonda Paris, Madrid).—*Field.*

The Cannon-Ball Tree.—Mr. Jenman, the colonial botanist at British Guiana, sends us a photograph of the flowering and fruiting stem of a young Cannon-ball tree, taken in the Promenade Gardens, Georgetown, British Guiana, which we have had engraved. This particular tree, which, as will be seen, is well named, is about 45 or 50 feet high, with a stem 18 inches thick, free of branches, as shown, and with a handsome spreading, hive-shaped head of dense dark green foliage. This is a young tree. In its native forests it grows to a much greater size. Couroupita guianensis inhabits the wide-stretching alluvial lands skirting the rivers of British Guiana, where it is plentiful, attaining a height of 80 to 100 feet or more. It is of free growth, and quickly forms a fine feature as a specimen plant in a tropical garden. It suddenly drops its leaves in March, and in a few days is again clothed in fully developed foliage of the richest green. The flowers are large, freely produced, curious in form, pink in colour, and highly scented. The solid rusty-coated fruits are about 6 inches in diameter, and contain a quantity of flat circular seeds, rather larger than a sixpence, embedded in their pulp. The tree belongs to the Lecythis family, and it is stated that the hard shells of the fruit are used as drinking vessels.—*Gardeners' Chronicle.*

Auction Sale of Cinchona Bark.—Messrs. Oakes & Co., under instructions from the Deputy Conservator of Forests, in charge of the Government Cinchona Plantations, sold by public auction, at their Sale Rooms, Exchange Hall, Madras, on Monday, 20,000 lb. of Cinchona crown and red barks in lots of about 100 lb. each. The attendance at the sale was influential and the bidding brisk. The following table shows the prices realized as compared with those of the sale on the 11th January, from which it will be seen that rates ruled considerably higher:—

Description of Bark.	Weight of bales lb.	Jan. 11. R.	Sept. 4. R.
Mossed Crown* ...	104 to 108	343—345	353—360
Natural* ...	102 to 107	243	245—267
Branch* ...	104 to 111	average	60
Natural red† ...	102	111—120	121—126 bale of 100 lb.
Mossed red† ...	100	147—151	158—182
Do‡ ...	102	none	170—172
Branch red† ...	102	73	73
Do‡ ...	102	81½	80

This result will, no doubt, be very satisfactory to Government, and will induce them, as well as private growers, to dispose of their produce in this market, rather than run the risks and delays of consignment to England.—*M. Mail.* [The *Madras Standard* adds:—The purchasers were Messrs. Arbuthnot & Co., Dymes & Co., Mr. F. M. Bowden, Mr. Croysdale, and Dr. Currie. The latter purchased about one-third of the quantity. The sale realized about R35,000.]

Correspondence.

To the Editor of the Ceylon Observer.

NITRATES IN AGRICULTURE:

THE PAST AND FUTURE OF COFFEE PLANTING—LOSS FROM BURNING WEEDS.

August 28th, 1882.

Dear Sir,—In his closing remark in your issue of 22nd inst.—"and further that it is not to the loss of nitrates that we are to look for the explanation of our present short crops."—"W. D. B." does not directly tax me to the contrary, and this remark may not have been especially, or in this sense, directed against my previous letters. But it is a point I am anxious not to be misunderstood on. Nothing I have said can be fairly construed into implying this. On the contrary, the widespread and persistent short crops of late years, I as fully feel, are to be attributed to other causes. This is the more manifest in the face of shortcomings, even when cattle dung has been liberally applied. All I have supposed, and venture still to say, is that, as in the case of, I believe, every other cultivation, nitrogen is a most important element both in the economy of the plant and for the development of the bean. The same can no doubt be said with equal truth of phosphoric acid, potash, lime, &c. Does not M. Ville in other words tell us so?

But to turn the tables: "W. D. B."'s letter would almost permit the inference that he regards nitrogen as an item of comparatively small importance, or that it is forced on us naturally, in our excessive rainfall so liberally—a sufficiency of the latter being absorbed as it is—that the subject is at least one proprietors need not feel anxiety on or trouble their heads about! Now—without referring to Hughes or the many other agricultural scientists, who, even before they knew of losses that may be attributable to nitrification, laid stress on the importance to us of abundance of nitrogen, —it is here I certainly cannot agree with him: that after a series of years, during which little has been removed by crop, or in soil known meanwhile to be rich therein, he is right in confining manuring operations to the application of phosphoric acid, potash, &c. In fact, whatever his soil is deficient in, in what the chemists would call "an elegant form," I fully believe. But wait a wee! It stands to reason that, given 4 lb. of beef—though it may amply suffice for 4 days—if you will allow your dog to steal half of it, you must lower your condition on insufficient rations, or at the end of the second day *purchase* fresh supplies. And so, depend on it, your correspondent will find. With but short crops, and as long as the soil contains abundantly an unexhausted store of nitrogen, extraneous supplies would be waste, and may for a long time be found unnecessary. But let, as I hope, and it would so far lead us to anticipate, his present system of manuring result in continued crops of 7 to 8 cwt. per acre, my belief is that he will find the supply insufficiently maintained by the small proportion of the amount nature offers through the medium of rainwater which he cares to accept under the present system as it stands. He will then see the necessity of devising means to do, as I said: "clean rob every drop that falls of all its riches." And further than this, unless by some means an entire check be placed on losses by nitrification, I venture to believe that it won't be many years before he is in the market for *beef* (nothing in reality better for the purpose!)—or shall we say white castor cake!! Further, if, as I confess I infer, he has such an entire confidence in the superabundant amplitude of our natural supplies of nitrogen, it leads up to a conclusion that the high value hitherto set on cattle manure (and especially cake fed) is little better than a popular delusion, for, though it be true that it contains phosphoric acid, potash, &c., in fair quantity, nitrogen is, or I am wrong, its dominant element of fertilization, and the one on which its value has been considered *predominantly* to rest—a conclusion I don't think many of our most experienced planters will readily accept! I grant though that I have often thought that, if, by the application of gypsum, or otherwise, the ammonia in it could be *fixed*, a *very great* saving in the cost of application (transport) might be effected—on the presumption that this would permit of the manure being *dried*, thus ridding it of a *very heavy* portion of its extraneous matter in the form of *sterile moisture*. I believe it is right to say that M. Ville disapproved cattle manure only as being a *clumsy* manure; and that he attached no less importance to nitrogen in abundance, I think the following extract shews conclusively:—"Professor Ville found that the conditions most favorable to fertility consisted in the union of 4 substances, *nitrogenous matter*, calcic phosphate, potash, and lime, to which he has given the name of *normal* manure. His experiments with these materials were most interesting. Without manure at all, the soil produced 12 bushels of wheat. With chemical manure, but without nitrogen, the yield was 18 bushels. Treated with nitrogenous matter but without mineral the yield was 22 bushels. But treated with *normal* manure the yield jumped up to 50½ bushels per acre!"

It is adverse to sound argument, and to resolve a discussion into a waste space and paper, to attach meanings to a writer that cannot be fairly construed from his words. I would therefore carefully guard against implying that "W. D. B." attaches *no* importance to nitrogen; but that he *does seem* to be over-confident of the magnitude of our natural supplies, or too lightly regards the necessity of conserving those supplies; that he does not apparently consider that, if the days of abundant harvest return permanently, any losses in this direction will have to be made good at their equivalent value *artificially*, if I interpret his views rightly. Your correspondent may be right but I think not. It is true I did not take the power of suction exercised by covered-in drains into account, and, if it be a power, this truly would point to less loss by a system of open drains. But it must be remembered that, in the Rothamstead experiments, drains but 20 inches deep carried off the largest quantity of nitrates; and he cannot surely mean that *none* but the surplus surface water passes into *uncovered* drains; that a large quantity does not in times of heavy rain filter through the soil into them, or that this water contains no appreciable proportion of nitrates? Again, *allowing* that the nitrates do all sink down into the subsoil, is he justified in assuming that they remain indefinitely, or for a sufficient length of time, within access of the roots? I make no *assertion* to the contrary but are there not stronger reasons for supposing so in the case of a free soil? Can "W. D. B." say that on digging out old bushes he has found the roots to a depth he would, judging from Mr. Warington's experiments, believe sufficient, and in sufficient numbers, to take them all up again as required? Or on a stiff, claycy soil, presuming that this does absorb and retain the nitrates near the surface, does not the manuer in which the roots of a well-grown young plant are often to be found confined within the hole cut for it, as in a flower-pot, lead to a doubt whether the roots of even an old tree can get at them in such a soil with sufficient readiness? Convert it into a free soil by cultivation, digging, &c., without some counter-check, you at once open the door to their escape? If it be true as to the power of clay soils to hold nitrates or check nitrification, it may account for their often great fertility when worked up and sweetened by lime, draining &c. That "W. D. B." sets no too high a value on

a limestone bottom, I firmly believe ; and that this equally applies to cinchona as to coffee—instance Jamaica ! Though a clay soil, the limestone it rests on affords perfec drainage ; and hence I fancy the reason we do not hear of the former dying out there." I well remember too poor "Squatter" Davidson (a far above the average well-read, well-informed, man he was ; as other members of his family, a keen observer of anything connected with natural history. and a good talker to wit : one I never wearied of listening to—except only perhaps it might be on one subject—and, as others too out here, I don't doubt, would gladly add, many a pleasant hour I have spent at his fireside at Hatton, so doing !) attributing the exceptional crops of a certain locality —I think in Dimbula somewhere, but am not certain—to its *limestone bottom* !

As to the suggestion of a protective crop of some sort to be grown amongst the coffee : that the idea occurred to, and its adoption recommended by, so good an authority as Liebig, I think entitles it to consideration. And further that it has received a long and successful trial already in Ceylon, I venture to name Alloowiharee : there the whole surface was permitted to become covered with moss (a velvetty, olive-green moss as far as I remember) with a view to check wash, which it would seem to do effectually ; but probably too, more than this, in the conservation of nitrogen. Still, though naturally a rich soil, I think on enquiry it will be found that it was necessary to apply liberal supplies of the latter *artificially* in order to support and maintain the *splendid* crops it notoriously gave, year after year, for years, and for ought I know may still be giving. Save possibly to a partial extent, through wash and neglect, can "W. D. B." kindly name any other sufficient cause than a waste of nitrogen and refusal of nature's supplies for the deplorable contrast that I fear has prejudiced many a passing visitor to Kandy unfairly against the coffee enterprize generally in Ceylon between the terraced paddy fields, that I suppose for generations have retained their fertility, to be seen on the righthand side ascending the Kadugannawa Pass, and the adjacent melancholy-looking scrub grown on the hilltops with but a few coffee stumps remaining as a memento of the past ?

Apropos of your suggestion of rape as a green crop, and as possibly equally applicable to it, the following quotation may not be out of place :—"Leguminous crops generally flourish in soils containing little or no nitrogenous matter ; and not only so, but are able in some mysterious way to obtain nitrogen from the atmosphere, and to store up a portion in the soil. The fact is well know to chemists It has been proved that a soil from which two crops of clover had been cut, thereby taking away a large amount of nitrogen, is richer in nitrogen than before the clover was."

If so, how much more rich, had the clover only been dug in ! It has since occurred to me that every bundle of weed I removed to be burnt in anxiety to *clean* a certain property was equivalent to removing (instead of applying) a basket of grass-fed cattle-dung.

The following is the opinion of an eminent Professor of Agriculture at home (for which, by the way, to a neighbour of mine who studied under him, thanks are due) which may afford your correspondent "W." some clue in connection with leaf-disease. I think it is briefly thus : —" That different plants *inhale* and *exhale* different gases ; that consequently, if only one product be cultivated over large areas, the atmosphere becomes after a time *exhausted of the element it requires to inhale*, or that it may become poisoned by re-inhaling its own breadth ; and that thus a door is opened to the different blights that almost invariably put in an appearance under these conditions." But this theory would in the present instance seem to be entirely upset by the prevalence of the disease in Sumatra, Java, &c., where properties are all more or less detached. And it is curious to note that, whereas in these countries the climate is generally a humid one, in India, the dry districts (Coorg, &c.), as in Ceylon, seem to be comparatively but little affected by it ! X.

P. S.—Besides Mr. Bosanquet's success I heard the other day of a property in Matale on which the resident proprietor had, by systematic and judicious manuring, any how kept up the yield to an average considerably more than sufficient to enable him to gradually convert it into a cocoa walk "in embryo." These are no doubt but two instances among many, and why with good blossoming seasons in the future should it not be to the same extent general?

NATIVE-GATHERED CAOUTCHOUC.

Galkissa, Sept 2nd, 1882.

Sir,—I take the liberty of sending you, per this day's tapal, for your inspection, a ball of caoutchouc, discovered and taken by me from a certain species of the caoutchouc-bearing family indigenous to Ceylon.—Yours faithfully, F. SREWARDENNE.

[The ball sent to us is not like rubber at all : Dr. Trimen, who has seen it, cannot suppose it to be of any commercial value. Can our correspondent tell us the Sinhalese name of the tree from which he collected this ball ?—Ed.]

PREPARATION OF TAPIOCA.

Kalutara, 7th September 1882.

Dear Sir,—Having 4 acres of manioc ripe, and being ignorant of the manipulation of the root, I should be much obliged if you, or some of your subscribers, would let me know a simple way of preparing tapioca for the market, in return for which I will with pleasure give you the benefit of our experience with it here, along with figures showing the profit or loss, in the transaction, which will be a rough criterion for intending planters to go by.

The natives in this district willingly take up arrowroot and make it into very good flour for ⅓ share of the produce, but of the manipulation of manioc they are quite ignorant, refusing even an offer of ½ of the product.—I am, yours faithfully, W. L. F.

[Our correspondent will find in our Handbook for 1880-1, p. 400*x*, a paper by a Singapore planter describing the preparation of tapioca.—Ed.]

THE SOUTH-WEST MONSOON OF 1882 AND THE RAINFALL RETURN FOR BOGAWANTALAWA.

Delrey, Bogawantalawa, 7th Sept. 1882.

Sir,—The S. W. monsoon now drawing to a close has been admittedly one of the most severe on record, and the following results of observations taken here may be of interest to some of your readers. The mean temperature during June-August, as compared with the mean of the nine years 1872-80, was as follows :—

	9 years mean	1882.
June ...	65°·7	63°·5
July ...	65	60·7
August ...	65·4	62·7

shewing an adopted mean for the three months of 62·3° this year against 65·4°: that is a mean temperature for this period more than 3° below the average. The rainfall was :—

	10 years mean 1872-81.		1882.	
	Rainfall.	Days.	Rainfall.	Days.
June ...	14·72″	25·2	15·86″	29
July ...	10·26″	23·2	21·07″	30
August ...	7·70″	25·8	14·37″	30
For the 3 months	32·68″	72·2	51·30″	89

We have in different years experienced equally cold, wet and windy weather, but for periods more or less short. This year has been distinguished for extremes of cold, wet and wind continued throughout the entire monsoon period, and is quite exceptional. This has probably been still more strongly marked in places that are more exposed to the influence of the S. W. monsoon.

In July against 21″ rain here, upwards of 45″ were registered on an estate at the lower end of this valley, while on another estate near the hill-range above Balangoda the fall was about 13″ only.—I am, sir, your obedient servant, GILES F. WALKER.

THE PROSPECTS IN NEW ZEALAND:—THE OTHER SIDE.

Colombo, 9th Sept. 1882.

Dear Sir,—The letter appearing in your paper of last evening gives such a very different account to that which I have always understood of New Zealand (and my information has been derived from friends residing there) that I think the enclosed letter dated two days later than that of your correspondent may not be without interest. I therefore send it you to make any use you like of it. The position of the New Zealand Government stock in the London market certainly does not appear to me to bear out the sweeping accusations made by your correspondent, and conversations I have had with Sir Julius Vogel lead me to think that there is a very good field for enterprize in the colony, if the intending settler has energy, a small capital, and ordinary caution. At this time of depression here (temporary only I firmly believe), when some amongst us may be turning their attention to other colonies, I think it only fair to give any information that may throw light on the other side, and feeling that your correspondent has not written quite impartially must be my excuse for occupying your space. COLONIST.

New Zealand, 31st July 1882.

Yours of the 1st June to hand; thanks for it. I wrote you the second letter fearing the first had missed you, not having heard in reply. I find it somewhat difficult to reply to all your questions, but however will try to do so. In the first place the climate of New Zealand generally and this district in particular is good for Europeans. The death rate never exceeds 12 in the 1,000, whereas England's is something like 22—in fact, owing to the mildness of both summer and winter old people reach 100 often. If you bring the smallest sum mentioned, viz., £5,000, and purchase land at a fair market value, the returns ought to enable you to save money annually, but as for stating how much—no man in a young colony can do that; the price of everything fluctuates more than in an old colony. If I could purchase this place at £5 per acre which I cannot, as the agent for the owner asks £7 and in its present state carries 150 cows, 400 sheep. The total outlay say for stock 150 head at 70s, £525; and 400 sheep at 10s, £200; rams bulls, horses, £100; total £825. Returns:—150 calves 30s £225; sheep, wool, £100; lambs £120. Total £440 at present market value. I pay £100 a year rent leaving £300 to the good to live, &c., and, as the land supplies all but labour and groceries, there must be a margin for profit. I have to live somewhere and have to pay rent; therefore on a farm a man lives cheaper than in a town. The place I am on is delightfully healthy; that is the reason I took it, and I presume I will end in purchasing it, as I have been spending money on it in fencing, draining, &c. This land is reckoned as good second-class. For first class land from £14 to £18 per acre is the present price. As many wealthy people are coming into the districts I doubt if there will be any decline in price. The market for stock is all local, as new lands are being opened up so is stock required. Cereals pay if you can get fair prices for what you grow. Wheat here is 4s 6d, oats 2s 6d per bushel. Of course new land where broken up is better for a crop, before being put into grass; so if the crop will pay the expenses it is free. The last land I had I sold for £18 10s per acre; that returned about four per cent. This place, if I gave £4,000, will return about 10 per cent, but in New Zealand in farming pursuits no man can determine what his income will be; stock fluctuates so very much. This time last year cows were worth £6, now about £4. But the success or failure of a man in the colony depends entirely on himself. Nature has done more for New Zealand than for any country in the world. I would not recommend any one coming here to invest all their capital in land and stock, but place at least one-third on mortgage at 8 per cent. The wages of servants here are about 15s per week for girls, £1 for men living in the house, man and wife about £75 per annum; day's wages of eight hours 7s, but all farm work I get done by contract. I am now trying to let some 300 acres of scrub to be cut by contract. I have a young man who looks after fences and stock, milks cows, cuts up firewood, &c. Round here there are some very nice people living, and with a pony chaise I think Mrs. —— if she likes the country would feel very jolly. The sporting season closes today, and I have had my share of longtails; have four hanging up now. When I get the land clean will be able to get more as I lose so many and require a boat or raft on each lake as the ducks remain in the middle and dogs are not always to be depended on. I think I have done what I can for you in answering your questions, but you must come yourself. All I can answer for is climate and soil. I have heard of one or two instances of moderate fortunes being made, but they are few and far between and then mostly among business men, but I think all settlers are doing well—at least but few complain and none fail.

THE CULTIVATION OF RUBBER: PRACTICAL EXPERIENCE; SHOULD LOCAL SEED FROM YOUNG CEARÁ TREES BE USED?

12th September 1882.

Dear Sir,—As indiarubber is to be doubtlessly one of the future great products of the island, it might be as well to consider the advisability of extending the cultivation by means of country-grown seed. With the exception of Peradeniya, there cannot be any very old trees, and therefore seed taken from young trees now may cause hereafter disappointment by the trees dying out. In some solitary cases I have found trees, after reaching 15 or 16 ft. before branching suddenly drop all their leaves and apparently die, or else hang for several months on the verge of it.

Perhaps some planter may be able to account otherwise for this peculiarity, but for my part I think it is from defective seed. There can be no doubt that canker in cinchona, where apparently the soil is perfect, can be only another name for bad seed, and so from past experience of cinchona we ought to be most careful how such a valuable tree as the caoutchouc tree is extended through the island. Could not Dr. Trimen be asked to pronounce his opinion, once and for all, as to whether it is safe to use seed from the young trees of the Ceará? Out of some 30,000 trees growing well and now over one year, I have had six cases of tall trees not having branched, casting their leaves; in two cases death was the result, and in four cases, after having for several months remained apparently so, they suddenly shot up again.—Yours faithfully, WATCHMAN.

TOBACCO CULTIVATION AND CURING IN THE NORTHERN PROVINCE OF CEYLON.

Report of the Government Agent, Northern Province, called for by Colonial Secretary's Circular of the 12th September, 1871, of the modes of culture, curing and manufacture of Tobacco as carried on in the Northern Province.

Tobacco is cultivated in this Province in all parts of the District of Jaffna, and in some villages of the Mullaittívu and Mannár districts. There is little or none cultivated in the Nuwarakálawiya district, owing very probably to the want of wells in that district from which to irrigate the gardens, the irrigation of tobacco being almost entirely carried on from wells and "thoravoes" as they are called (in Tamil ...,) which are merely temporary wells sunk in tanks and in sandy districts. The quality of the tobacco, of course, varies according to the nature of the soil, the quantities and description of manure used, the care and labour bestowed upon its cultivation, and the process of curing gone through.

The best smoking tobacco according to the native taste is grown in the Pachchilappalai, Púnakari and Tenmorachchi divisions of the Jaffna District, and in Illuppáikkadavai and Mantotte divisions of the Mannár District, and Puthukkudiyiruppu of the Mullaittívu District.

The tobacco grown in the Vadamorachchi, Valikamam East, Valikamam North, and a few villages in Valikamam West, in Jaffna, and in the Navakuli parish of the Tenmorachchi division, and Allaippiddy of the Island division, is considered the best for export to India and for the markets of the Southern, Western and Central Provinces of this Island.

Seed.

In each garden one or two plants are allowed to run to seed in order to supply the seed for the next season. The heads of the plants, on which are the seed pods, are cut off and left in the sun, and when sufficiently dry are kept wrapped up in clothes or in baskets and hung up in smoke till next season.

Process of Cultivation.

The cultivation of tobacco is carried on in what is called "garden lands," and sometimes in paddy fields immediately after the harvest. After the tobacco crop has been taken off the "garden lands" they are sown with fine grain the heavy manuring required for the tobacco being availed of for the dry grain cultivation.

The cultivation is commenced about the end of October and continues to about the end of April. The seed is sown in nurseries. A nursery consists of a small patch of ground raised about one foot from the ordinary level and heavily manured with different descriptions of leaves and cattle or goats' dung. The seed is sprinkled over these and covered with thin layers of earth and pressed down with the foot and completely covered with cocoanut or palmirah leaves. Water is sprinkled over them once a day. In about eight days the cocoanut or palmirah leaves are removed. When the seeds commence to germinate a "pandal" (...) two or three feet high is placed over them to shelter them from sun, rain and dew, and they are daily sprinkled with water for about ten days. The cover is then removed, and water is sprinkled once a day for another month, at the expiration of which time, if the seedlings are found to be too close to one another, another bed similar to the nursery bed is prepared, into which some of the seedlings are temporarily transplanted, and sheltered as before for about eight days. In about $2\frac{1}{2}$ months from the time of sowing the seedlings are transplanted into gardens which have been prepared for them in the following manner, viz :—When the seed is first sown in the nurseries, the preparation of the garden is commenced by manuring thus,—by penning cattle on them and thus securing the dung, by burying leaves of various descriptions in them, and by folding goats or sheep in them in order to secure the manure, or by spreading cow dung over them. They are then ploughed, and about the middle of January holes for the reception of the young plants are made about a yard apart, in which cattle manure and leaves are buried, and one or two seedlings planted in each, which are covered over with small boughs of trees and leaves to protect them from the sun. The young plants are watered once or twice a day, as necessary, for about fifteen days. The ground around the plants is slightly hoed, and they are kept without being watered for a day or two. At about this time if any of the plants die they are replaced. After ten days the land is again hoed and left for one or two days to dry. Furrows are made between the plants, with smaller furrows to the roots of each plant, and water is passed through them all so as to wet the roots of the plants without wetting the intervening spaces of ground. Cattle or goat dung is again spread over the land, which is again hoed and levelled, and the earth is hoed up round the plants and left for two or three days, and then formed into small squares enclosing two or four plants so as to form small reservoirs round them, into which water is conveyed every other day. By about the 10th of March the plants begin to blossom, and the tops are lopped off leaving about twelve leaves on the stems, the lopped-off tops being left on the ground. Any off-shoots that may appear are carefully removed. About from forty days to sixty days after lopping, according to the nature of the soil, the leaves will be fully matured and ready for cutting. The tobacco plants are subject to damage or injury by insects and various worms called Alukkanavan (...), Kottián (...) and Erivandu (...) The cultivators are obliged to carefully pick off those insects immediately from the plants. The insect (...)

appears when there is an absence of rain for any length of time. If the plants are allowed to run to seed the quality of the leaves is affected, they become small, get brown, wither and fall off.

There are three descriptions of leaves taken from each plant—the first sort, Terivu (தெரிவு), the second sort Idai (இடை), the third sort Sachchu (சக்கு). The number of leaves on a plant averages from ten to twelve of which there are of the first sort five leaves, the second sort two, the third sort three to five. The first sort are the upper leaves, the second sort the middle leaves, the third sort the bottom leaves.

Curing.

When the leaves are ready for cutting the general practice is to cut the plant off short, and leave it on the ground. The leaves are then cut with part of the stem attached to them and left in a heap for from one to three days, according to circumstances; they are then taken up tied together in bundles of about five and hung up in the smoke in a kudil (குடில்), or hut, closely walled round with mud and cadjans and smoked for a day or more. The leaves are then taken out and hung up in the shade in the air, and when quite dry they are piled up and pressed down. The bundles are then untied and the leaves sorted, and again tied into bundles of 50 each and piled up into heaps. The tobacco made by this process is called Veliaichcharakku (வெளிச்சசரக்கு). Another process, by which what is called the Karuppucharakku (கறுப்புசரக்கு) is cued is as follows:—After the plants have been cut and left to the action of the sun for some time, they are hung for three days in the air in the shade and then the leaves are separated allowing part of the stem to remain with each leaf; they are then buried in heaps of cowdung, either fresh or old, or are buried in trenches in the ground and allowed to remain for about three days; they are then taken out and tied in bundles of five each, and smoked, and then left for three days "to cool," as it is termed, and then piled in heaps, covered and pressed; they are then again hung up and smoked and left hanging in the kudil, or hut, for from two to four days: they are then taken down, sorted, made up into bundles of 50 leaves each, and heaped.

The first process of curing is carried on in general with regard to tobacco exported to India; the second with regard to smoking and chewing tobacco and tobacco exported to the markets of Galle and Colombo.

Manufacture.

The only manufacture is that of cigars of a rough description. The process of curing the smoking tobacco has already been referred to.

The process of manufacturing in some places is merely to roll up pieces of tobacco in a good leaf, and tie the end up with a thread. Another process is to soften the leaves with fresh water, the first sort being used for the outside and the second sort and broken pieces for the inside. The cigars are tied together in small bundles of ten, and a decoction (கஷாயம்) prepared by boiling the tobacco fibre in toddy, arrack, or young cocoanut water is sprinkled over them, and they are then packed in boxes containing from 20,000 to 50,000 each. This decoction (கஷாயம்) is used not only to increase the flavour of the cigars, but it is also to preserve them from injury by insects. A coarse description of snuff is prepared (but in no great quantity) by roasting the tobacco leaves of the first sort in fire and reducing it into a thin fine powder and mixing a small quantity of chunam to increase its strength. This manufacture is entirely for local consumption.

The greater portion of the tobacco grown in the Jaffna Peninsula is exported in leaf to Galle and Colombo, in the Island, and to Cochin and other parts of India.

What is called the first description is exported to Galle and Colombo; the second description and any surplus of the first description to Cochin, &c.; the third sort is principally taken to Mátalé.

For export, the tobacco is tied up in bundles called "sippam" (சிப்பம்), which are nothing more than bundles of tobacco weighing from 75 lb. to 1½ cwt., pressed and tied up in ola (palmirah leaf) mats.

The bales of tobacco sent to Galle and Colombo weigh from one to one and-a-half cwt. The bales exported to Cochin weigh generally about three quarters of a cwt.

The tobacco exported to India is sprinkled with salt water before being tied up in bales.

From 1858 to the end of 1869 an export duty of 4*d.* a cwt. was levied on tobacco exported beyond sea. This duty was abolished in 1870 with other export duties.

The annexed statement, furnished by the Customs, shows the quantity and value of the tobacco exported beyond sea and coastwise from 1856 to 1870, and the duty recovered on that exported beyond sea.

I have no means of ascertaining the quantity taken to Mátalé by land. I believe it to be between 3,000 to 5,000 cwts. annually, and that consumed in the Province would be perhaps 9,000 cwts., which will make the total annual crop from 50,000 to 60,000 cwts., and the value from £80,000 to £100,000.

The extent of land cultivated with tobacco in the Jaffna Peninsula must average about 4,500 acres.

The average price of the tobacco is as follows:—

	£	*s.*	*d.*		Rs.	cts.		
First sort ...	3	0	0	or	30	0	per cwt.	= 1,440 leaves.
Second sort ...	2	2	0	or	20	0	do.	= 2,880 do.
Third sort ...	0	16	6	or	8	25	do.	= 4,320 do.

The following is an extract from a report made to me by the Second Mudaliyár of the Kachchéri regarding the cost of cultivating and the yield of an acre of land in the Jaffna Peninsula.

"To grow tobacco in a piece of land, not less than three people must form a company, for, in the manner plantations are watered in the Jaffna Peninsula from wells, the work cannot be done by a less number; but in some villages of Tenmarachchi and in the Pachchilappali, Púnaryn, and the two districts of Mullaittívu and Mannár, where the plantations are watered from Thuravoo (ஊற்று), or temporary tanks, one or two people can cultivate a piece of land, and the extent of cultivation will be very much limited. The quantity of tobacco yearly cultivated in the latter being comparatively very small. I think it right to pass over such manner of growing tobacco in illustrations

"The three people in a company can cultivate tobacco on an extent of one acre during one season of a year. The rent of four lachams (1 rood) of tobacco ground varies from 15*s.* to 40*s.*, and at that rate rent for an acre will be £3 to £8 (Rs. 30 to Rs. 80).

"The cultivation for a season will occupy their labour for six months; the value of their labour at 15*s.* each per month for three people for a period of six months will be £13 10*s.*

"The people commence to manure and prepare the land for tobacco in October or November, and the land is first manured by penning black cattle; these cattle are either procured from their owners for feeding, or they are the property of the cultivators themselves, and they do not pay for this manure; but it should be observed that to keep up the black cattle in the winter, by feeding them entirely with grass, will occupy nearly the whole time in the day. Again, the cultivators bury green leaves. One cartload of green leaves will be wanted for a lacham, and at that rate 16 cartloads for an acre will be, at 5*s.* a cartload, £4.

"Again, the land is manured by sheep: 60 paddies (பட்டி), each containing 100 sheep, will be required for four lachams, and for an acre extent 240 paddies (பட்டி), and one paddy (பட்டி) manure will cost at least 1*s.*; for an acre extent £12. Total cost, £32 10*s.* to £37 10*s.* (Rs. 325 or Rs. 375).

"When I submitted a paper to the late Mr. Dyke some several years ago, I had calculated on 1,000 plants to be planted in every three lachams. Since that, as people began to apply more manure and to raise the quality of tobacco, it is found necessary now to plant 1,000 for every four lachams—so in an acre of land 4,000 plants are planted.

"The tobacco planted in a very good soil and in a highly manured land will yield—

				£	*s*	*d.*		Rs.
1st sort	leaves	5 for 4,000 = 20,000 at £2 per 1,000	...	40	0	0	...	(400)
2nd	,,	2 ,, 4,000 = 8,000 ,, 15*s.* ,,	...	6	0	0	...	(60)
3rd	,,	3 ,, 4,000 = 12,000 ,, 5*s.* ,,	...	3	0	0	..	(30)
		The produce of an acre ...		£49	0	0		(Rs. 490)

"The difference between £37 10*s.* (Rs. 375) and £49 (Rs. 490) is the profit, and for each of the cultivators the profit will be £3 15*s.* (Rs 37·50). This profit the cultivators can yearly expect if the market price in Travancore does not fall to what it is now, and if the tobacco crops have not met with heavy rains or gales when they are in plants.

"When the cultivators do not take lands on rent the owner of the lands defrays all expenses and divides the profits into nine shares, and takes six shares for himself, and the three shares are divided among the three cultivators, which will give nearly £5 10*s* each; and cultivating on "varam" is much less profitable to the cultivators, for, in the other case, an amount was allowed as hire for their labour, and in addition to that there is a profit of £3 15*s.*

"Much of the cultivation is under the latter system—that is, "varam."

"True copy."

W. C. TWYNAM,
Government Agent.

Jaffna Kachcheri,
30th December, 1871.

Notes referred to.

1.—*Tobacco.*

The best smoking tobacco is also grown in the divisions of Achchelu in Valikámam East, and Chutumulai in Valikámam West.

2.—*Process of Cultivation.*

As a general rule, immediately after manuring, the ground is first hoed and then ploughed as often as is necessary to fit it for planting the seedlings.

3.—*Description of Leaves.*

The second sort (இடை) generally averages from three to five leaves, and the third sort two to three leaves.

4.—*Manufacture of Snuff.*

In addition to chunam, a few drops of gingely oil or cow-ghee is also used to increase its flavour and to preserve it from damage.

5.—*Extent of Cultivation.*

The extent under cultivation at present must average about 6,000 acres, showing an increase by one-third of what was cultivated in 1871, and the total annual crop would be fairly estimated from 70,000 to 80,000 cwts.

The largest export beyond the Island was 41,986 cwt. in 1880.

Manuring.

The following leaves are generally buried for manuring the ground for cultivation of tobacco:—Pannai (பணை), Káviláy (காவிளாய்), Kaiñai (கைஞை) Ikkeeri (இக்கிரி), Chatturakkally (சதுரக்கள்ளி), Kándai (காண்டை), Pirandai (பிரண்டை), Kaddámanakku (காட்டாமணக்கு), Chooria (பூவரசு), Vedduk-kunáry (வெட்டுக்குநாறி), Margosa (வேப்பு), Punku (புங்கு). One cartload of the above leaves, &c., would cost from 2 to 3 rupees.

Smoking.

Cocoanut husks and dried nuts of palmirahs, with other common firewood, are used for smoking the tobacco.

"True copy."

W. C. TWYNAM,
Government Agent.

LETTING A FOREST.—The deer forest of Dundonell, in Scotland, on the estate of Mr. Mackenzie, of Dundonell, has been let at a rent of nearly £3,000. This forest, including Gruinard shootings, extends to upwards of 60,000 acres.—*Scotsman.*

RAISING PALMS FROM SEED.—The great demand for Palms, especially in a small state, makes the production of these a matter of some moment. Some raise their plants from imported seeds; others, who grow on a less restricted scale, purchase seedling plants on the Continent and grow them on into size until fit for sale. Those who raise from seed obtain their seeds from various parts of the world at all times of the year. Mr. F. Bause, of the General Horticultural Company's Melbourne Nursery, Anerley, raises annually a large number of Palms, and whether the species and varieties require warm or cold treatment all are treated alike in the matter of raising plants from seed. The seeds are sown as soon as received in pans and shallow wooden boxes; the soil used is turfy loam and a little sand, and the seeds are covered about an inch or so. In raising Palms from seed the great point is to get the seed as fresh as possible; and, if perfectly fresh when received, Arecas will germinate in six weeks, and Cocos Weddeliiana in about the same time. Euterpe edulis is quicker in germinating. A few sorts lie in the soil longer than others. Bactris requires twelve months to germinate; one or two at a time will come earlier, and at intervals, but the bulk take the length of time named. Elais guineensis requires the same period before the cotyledons appear above the soil. The principal Palms raised from seed in this country are:—Euterpe edulis, Areca lutescens, Cocos Weddelliana, C. flexuosa, C. amara; Bactris Binoti, Geonoma gracilis, G. Schottiana, G. Seemanni; Thrinax elegans, T. parviflora; Kentia australis, K. Fosteriana; Caryotas, Latania borbonica, L. rubra, and L. aurea. The matter of potting from the seed-pans is one of some importance. Mr. Bause pots within a reasonable time after the plants are something like established in the seed-pans, but it is well not to pot too soon. Each plant is placed individually in a small pot. Some sorts show their peculiar leaf character sooner than others. Latania borbonica will do this in from one to two years; Geonoma shows its character in quite a young state, and Cocos Weddeliana does the same. C. flexuosa not so soon. It is a practice full of interest to the grower to what the gradual development of character in the young plants as they increase in size and vigour.—*Gardeners' Chronicle.*

THE JUTE INDUSTRY OF DUNDEE.—By the American Consul Winter.—A Dundee manufacturer, who has frequently passed through Ceylon en route to India, and who is well acquainted with the nature of the climate and the soil of that island, has asserted that jute is a product suited for cultivation there, especially in the south-west side. There has, however, been no action taken upon this suggestion.—*United States Consular Report.*

THE POTATO DISEASE.—A constant succession of small showers is, by the promotion given to the diffusion of the Peronospora spores in the Potato plant, very rapidly bringing about the defoliation of early sorts, and with many kinds hardly a green leaf is left. With the second early sorts the black spot is very abundantly visible, whilst the later kinds, having stout robust growth and vigorous leafage, exhibit evidences of the fungus only here and there. Naturally growers are seeing these disease aspects with considerable alarm, and their fears are not allayed by the too frequent evidences of the presence of the disease in the tubers found on lifting the roots. The theories so ably propounded by Mr. Jensen have naturally set intelligent growers thinking, and though many have found it too late this year to test his plan of protective moulding, yet they have tested it so far as to ascertain whether the spots of disease now too evident in the tubers bore evidence of external or internal attack. Our own experience so far has resulted in the finding of the disease spots chiefly upon the tubers nearest to the surface, and on the upper sides, except in cases where the basin that inevitably exists around the stems earthed-up in the customary fashion has facilitated the carrying of the water down into the nest of tubers at the base of the stems, and there disease has been found in various places on the tubers, some small ones being entirely affected. With our crops in their present somewhat diseased state, the ordinary practice with many growers would be to pull the haulm and remove it; but there now follows the danger that the loosening of the soil consequent upon the pulling of the tops and the inevitable drawing of the tubers nearer the surface is calculated to do more harm than good. Disastrous results, too, have so often followed upon very early lifting and storing, that it renders Mr. Jensen's advice, to allow the tubers to remain buried until the fungoid spores are no longer active in the air, as of momentous importance. It cannot, however, be too clearly understood that such advice is intended to apply to crops that are moulded as he advises.—*Gardeners' Chronicle.*

BLUEGUM AND WATTLE SEED.

TO THE EDITOR OF THE "AUSTRALASIAN."

SIR,—What is the usual quantity of Tasmaoian bluegum seed sowu to the acre (broadcast)? Also, should wattle seed be steeped in hot water previous to sowing; if so, for how long, and at what temperature should the water be when the seed is put in? SUPER COMBING.

Amuri, New Zealand.

[Two ounces and a half good bluegum seed will be enough for one acre; plough very shallow and harrow fine before sowing. 2. Pour boiling water upon it, and set it aside to cool. If the bulk be large, use shallow pans; leave it to soak until it swells.—EN. *Australasian.*]

HOUSEHOLD PRESCRIPTIONS BY "HAKIM."

The prescriptions 1 and 2 are said to be infallible. I have not tried them but my friend has, with glorious success in almost hopeless eases. A trial is requested, and tho result to be communicated to the *Asian.*

(1.) MANGE IN HORSES.—Take a few pounds of the refuse mhowa (*Bassia longifolia*) flowers (after distillation) and grind into a paste; then rub it well into the eruption, letting the paste to remain on for about four hours, after which wash it off with warm water and country soap. One application a day for a week will suffice to eradicate the disease.

(2.) MANGE IN DOGS.—Reduce a quantity of the blighted stalks of the milkhedge (*Saindh, Thur,* Hindustani; *Kulli,* Tamil) to powder, and mix with linseed oil to form a paste, after which rub the diseased parts well with the paste, and allow it to remain on for a couple of hours, then wash off with soap and tepid water. Apply only once a day. A teaspoonful of sulphur, mixed either with milk, butter, or ghee, to be given every morning for three days. Diet light.

(3.) TICKS ON FOWLS.—Common salt, mixed with cocoa-nut oil, is an effectual remedy. The *B. flats* begin to get stiff and fall off within a couple of hours; after which time the fowl is to be sponged with lukewarm water. There is no use applying the above solution if the "moorghi-khana" is a receptacle for these abominations. Exterminate them by filling up all cracks in floor and walls with mortar, and then lime wash. This latter is to be done once a week. The "bloodsuckers" not liking water prefer leaving the geese and ducks alone.

The Deccan, August 1882.—*Asian.*

GUINEA GRASS.

Enquiries having been made by several of our friends respecting the merits of Guinea grass as feed for stock, we give the following remarks from *The Southern Cultivator,* which owes them to the *Florida Agriculturist*:—

Guinea grass (Panicum jumentorum) is first mentioned in connection with the Island of Jamaica, where it was accidentally introduced about one hundred and fifty years ago. A present of some beautiful birds had been sent to a lady in Jamaica by a friend on the Guinea Coast. After their arrival in Jamaica the birds died, and the seed which had been sent with them was regarded as of no further use, and was thrown out into a hedge. Some time afterwards it was noticed that cattle kept lingering about that particular spot, trying to get at something in the hedge. This attracted attention to the grass, and it was henceforward cared for. It has since spread over the whole island, and also the neighboring West India Islands. In Jamaica large tracts of country are kept planted with it, and the finest horses and cattle are reared upon it. There is no need of planting it every year. Some fields have been seeded over one hundred years to this grass without being renewed or manured. The fields are usually closed up twice a year to allow the grass to grow to the proper height and ripeness before turning in the stock to feed it down. The droppings from the cattle and the quantity of grass trampled into the ground are sufficient manure. When the fields are kept for cutting purposes they are manured once a year, the grass being previously fed down before the rainy season, and manure scattered over the roots, to be washed in by the rain. In parts of Jamaica it grows much more readily than in others. In some parts the wood has only to be cut down and burnt off when the field springs up in fine Guinea grass. In other parts the plant must be carefully cultivated. Although only one variety of this grass was taken to Jamaica the climate has somewhat changed its nature, so that I (Editor *F. A.*) know of three varieties. Every estate or coffee property keeps fields of the grass for cutting purposes, and stock are entirely fed upon it. I have never known the estate mules to get grain of any kind, and if offered to them they would probably not eat it, yet they are as hard worked as any animals in the world. In Jamaica the Guinea grass is seldom propagated from seed, but from the roots of old plants, which are taken up, separated, and re-planted in small holes dug with the hoe. This practice may arise in part from the hilly nature of the island, which often renders ploughing impossible.—*Queenslander.*

TREATMENT OF THE PEACH TREE.

From the proceedings of the Agri-Horticultural Society of India, we quote hints for the treatment of about the most useful and successful fruit cultivated in estate bungalows in Ceylon:—

Submitted the following account from Mr. O. Nickells, of Jaunpore, of the result of his treatment of the Peach tree:—

"I have been very successful with peaches this year, both as regards size and quality, a tree upon which I had been experimenting having yielded fruit 8¼ inches in circumference and 4½ ounces each in weight, and of very fine flavour. The following is my system of treatment:—At the close of the rains, or about the 15th of last October, I laid the roots of the tree in question bare for about 4 feet all round from the stem. By the 1st December the tree had ripened its wood and the leaves had nearly all fallen. I immediately pruned it and pulled off the few remaining leaves. The roots were then covered with dry well-decayed cow-house manure, and over this a thin layer of earth. About three weeks afterwards the tree was in full bloom, and when the fruit had set I began irrigating it. My plan is always to give plenty of water. After a little while I thinned out the fruit, allowing only one to remain upon each shoot. All the time that the fruit was swelling I gave it *liquid manure* prepared as follows:—Two parts fresh goat's dung, two parts *oil-cake,* half part *soot,* and half part *lime.* This mixture I put into earthen jars buried in the ground, about half the jar being filled with the mixture, and then filled up with boiling water and kept closely covered. The liquid manure was prepared two months before it was required, and the tree got about three gallons of this mixture diluted with a large quantity of water once a week.

'Next year I hope to produce finer peaches, if that is possible. I think rotten fish might be added with advantage to the liquid manure, and *bone*-dust to the roots. I'll try the experiment at all events.

'Would you like to have a few grafts from my tree for the Society's Garden? If so, I shall be happy to prepare them for you, or I could send you cuttings during the rains for budding, *i.e.,* if this operation can be successfully performed in Calcutta. The fruit is of considerable beauty and fine flavour, and the color of the flesh is pale with a slight tinge of red next the stone. I need not say there is not the least taste of bitter in it, as is so common."

HEDGES OR LIVE FENCES IN AUSTRALIA.

Many species of plants have been pressed into the service, to do duty as apologies for hedge-rows in small, as well as around large gardens in the colony, and not a few attempts have resulted in utter failure, whilst numerous instances of very partial success occasionally meet the eye in suburban as well as in more remote districts. But where can one see anything approaching to the luxuriant and well-kept hedges of old England? Does not the hawthorn thrive in this climate splendidly, and grow luxuriantly, with its white pearly blossoms and fragrant perfume. First and foremost, then, may be placed the white thorn as a popular hedge-plant; it stands without a rival for such a purpose, and requires cutting only once

a year, whereas other substitutes need no end of attention —such as the acacia lophantha, which impoverishes the soil wherever it is planted. Acacia armata, or prickly acacia, has been largely patronised, but it has a tendency to get patchy and bare, and now presents a very sorrowful aspect around many a country and suburban garden. The arbor-vitæ, when duly attended to, does much better. The New Zealand pittosporum Eugeniodes forms a very beautiful garden hedge, and bears clipping remarkably well. The various kinds of cypress, such as erecta, torulosa, horizontalis, and lambertiana, as well as the olive and ceanothus, have all been used with more or less success, according as attention has been bestowed upon their cultivation. The common furze forms a capital live fence, but as it gets very dry, and susceptible of easy ignition when a little old, it is rather a dangerous subject to deal with in this hot climate. Then there are the *privets*, deciduous and evergreen, which make a very beautiful and ornamental fence; the Cape and prickly broom are also used for such a purpose, as well as the Chinese euonymus japonicas and variegatus, which also stands clipping well. The famous Osage orange (maclura aurantiaca) and Gleditschia, both from America, form fine strong hedges—many prefering the former to the hawthorn. Certainly the Osage orange makes a very substantial fence. Bursaria spinosa, a native of this colony, which flowers in January, is a very pretty ornamental shrub, and adapted for a garden hedge.

As already stated, however, there is no plant like the thorn so suitable for forming a hedge, not only for small gardens, but boundary fences, fields, and forest plantations. It takes well with richly prepared soil, and amply repays any extra labor in the due preparation of the ground for their reception, which ought to be well-trenched, and incorporated with a good supply of well decomposed manure. Any quantity of young seedlings can be obtained at the nurseries, but three-year-olds, twice transplanted, having fibrous roots, may be relied on as very satisfactory, When put in about six inches apart in the hedge-row, and headed down to within two inches from the ground, the following season numerous shoots will have burst forth. The erect mode of planting is preferable to the horizontal method, so commonly pursued in the old country. For a couple of years the plants may be left to their natural growth, but the third season brings round the trimming process, which may then afterwards be pursued according as the will of the practitioner may suggest. The usual form adopted is the wedge shape, being by far the most easily performed with the hedge-bill than the other modes that sometimes find favor. It is of paramount importance, in order to be successful, to see that the ground is always kept in good order on either side of the hedge.—*Town and Country* [N. S. Wales.]

PLANTS WITHOUT EARTH.

A certain amount of ingenuity may co-exist in an individual with a want of true perception of the value of a discovery or plan. Anyone who has observed the way plants grow need not be told that they are not always particular as to a "medium." If we bring a load of fine shell from the shore in winter, the first spring day it will be taken possession of by a number of plants, which will grow and flower well the same year. Cinders are not soil, yet a heap will soon get covered with plants by no means sickly-looking. Ferns, usually supposed to love moist rich soil, often thrive in the lime dust of a dry wall. We have often noticed the yellow fumitory high on an old fort, where soil or moisture in any ordinary sense did not exist. Cocoanut fibre—the detritus of the husk of a fruit—is chosen by gardeners for its excellent qualities in assisting in the growth of cuttings and young plants. Pure sand is used to a large extent for propagation; and we have seen very remarkable results obtained in striking fine-foliaged tropical plants in sawdust in M. Truffaut's nursery at Versailles.

We may take advantage of such facts, and learn something from them, without building unwarrantable assumptions thereon. This we may say of the growth of plants in moss—a somewhat recent French "invention," of which we have heard a good deal. This so-called discovery reveals to us that plants may be grown in moss without earth, though we already knew the fact that orchids grew often in moss, and even in air, without it or anything else. Moss is nearer in nature to soil than some of the abovementioned substances, and it has been used a good deal in various kinds of cultivation and propagation. In America, Peter Henderson, of Jersey city, has great success with sphagnum moss, used in a layer in seed raising; but no one has hitherto recommended it for use instead of earth. Mr. Dumesnil does this at last, and, judging by the exaggerated statements that have gone the round of the papers concerning his method, he has been busy urging its merits on those who take for granted all that is said on the subject. No one doubts, who has observed the above and many other facts, that plants will grow in moss. We often see them so growing in very mossy woods and on mossy rocks. Bog earth, used to a very large extent by itself for plant culture of various kinds, is mainly decayed and compressed moss. But these things would not justify anyone in giving rise to statements such as we give examples of from *Good Words*.

We ourselves tried this system as presented to us by the agents of the discoverer, and found, as we expected, that the plant—a Ficus—lived fairly well in the moist moss. There was no advantage in the case in having the plant in moss, because it would occupy no more space in good earth, which moreover would have been simpler and better for the house and its owner, as well as the plant; for the inventor, not having confidence in moss alone, saturates it with some chemical which to us, as tested in a large room, had a slightly cadaverous, offensive, though not strong smell. A pot of good earth never has any odour of the kind; but one could get that in the shed, whereas this prepared moss has to be bought like our patent medicines. The one use that such a plan would have is in enabling "floral decorators" to put plants in various elevated and awkward positions in rooms—in our country a matter of limited importance. If it would enable us to grow plants better indoors, the plan would be a gain; but it does not do this—on the contrary, it would make their culture more expensive and troublesome.

The following extracts from *Good Words* may serve to show the length to which want of judgment will urge persons who might write usefully if they would plead the claims of the no-earth plan in terms befitting its use and importance—and they are modest enough:

"A Russian lady, suffering from intermittent fever, was attended by Professor Edward von Eichwald, of St. Petersburgh. The disease readily gave way to quinine, but returned again and again in the most inexplicable manner. At last the cause was discovered; when she left her sick room convalescent she went into the saloon, a large room filled with plants. Professor von Eichwald ordered the room to be entirely cleared, and the fever returned no more. Such malignant effects are impossible with fertilising moss; it cannot turn sour like earth and poison the plants, or contain germs of malaria and poison their owner."

We need scarcely say here that various plants may be grown in a room without in the least tainting the air. The odour of certain plants in flower may be disagreeable, but there is nothing in a pot of sweet earth with healthy roots in it which anyone need fear. In the trial we made with this "fertilising moss," there was, as we have said, an odour which, to sensitive persons at least, would be offensive, if not injurious.

"The object in the cultivation of vegetables being increased and regular productiveness, the plan adopted by the gardener of Vasceuil is to place their roots, enveloped as above described, in an ordinary bed of mould. The results are most satisfactory. We saw at Vasceuil as many as thirty fine potatoes the produce of one mother-tuber. *Thus the poorest land may be made to teem with rich crops, the soil being of no importance*, the earth merely affording room and shelter for the plants. Seedlings and cuttings are raised in the same way. In fact, the process seems to have all the characteristics of a great discovery: perfection in principle and indefinite powers of further development. The discovery of a nourishment applicable to all forms of vegetable life is the primary fact in the Dumesnil culture. The fertilising moss agrees with every kind of plant, those that grow wild, as well as exotics, herbaceous, or ligneous, ornamental or for food. By its fostering power with plants, natives of the Pyrenees, the

Alps, the Carpathian Mountains, the Caucasus, and the Himalayas, introduced during recent years into English gardens, will, by this process, flourish under a simple glass all the year round."

These statements may be left to our readers' judgment, we think! Moss is a useful aid in its place, but much of the more important kind of plant culture in rooms may be carried on without its aid, and has as been so carried on for many years, in our own country and in others where room culture is more largely practised. It may be useful in various kinds of culture in light vessels or baskets for certain positions, but its use will be limited, by reason of the special sale of the fertilised moss as a patented article. Such merit as it has, however, should not be used to unsettle people's minds as to the value of soil, in the way of which we have given examples from a periodical of large circulation and influence.—*Field.*

ANALYSIS OF PHOSPHATES.

Professor Jamieson, of the Aberdeen University, has recently drawn attention to this subjet in a short pamphlet, which is of such importance that we regret our inability to reproduce it *in extenso*. To the ignorant and confiding farmer the opening sentence is sufficiently surprising—viz., that phosphatic manures do not, as a rule, contain the proportion of phosphate represented by the analysis by about 3 per cent. This error, it is stated, is owing to chemists using inaccurate methods of analysis. Those who do not use such methods suffer in their profession. Manure merchants naturally enough prefer to employ those who uniformly give high results. That farmers suffer through these unduly high analyses is undeniable. 3 per cent excess in bones alone would make a difference of £20,000 in the value of the Board of Trade returns; whilst on other phosphates the difference would probably amount to more than double this sum.

Mr. Jamieson next appeals to chemists engaged in the agricultural world to amend their practice, and proceeds to give a striking illustration of the evil complained of. The substance analysed was an undissolved mineral, chiefly composed of calcic carbonate in a fine state of division, remarkably uniform in quality, as proved by the analyses of two samples. This substance was analysed by six chemists, described as mostly well known, and representatives of manure analysts:

No. 1	found	10·80	phosphoric	anhydride.
No. 2	„	10·67	„	„
No. 3	„	10·30	„	„
No. 4	„	9·58	„	„
No. 5	„	9·18	„	„
No. 6	„	8·62	„	„

Professor Jamieson, having above results supplied to him, found 7·50 phosphoric anhydride, being 1·12 per cent below the lowest result, and 3·30 per cent lower than the highest, a difference equal to 7·20 per cent phosphate of lime. Naturally, Professor Jamieson's result was objected to, and a second sample sent, which produced 7·68 per cent, which is practically identical. Professor Church was suggested by Professor Jamieson as referee: the sample was divided into three portions, put into stoppered bottles, and sealed up. As to this proposition Professor Jamieson says: "The practice of sending reference samples to chemists largely employed by the trade, and known to be 'high,' is clearly absurd. Professor Church, not being in either of these positions, being well known in chemical science circles, author of an excellent work on Agricultural Analysis, and known to be painstaking, his name I felt satisfied would be accepted as satisfactory." The merchants did not agree to unite with Professor Jamieson in reference to Professor Church, but the sample was sent, and the following is his decision: "The mean of six determinations gave 8·06 as the percentage of total phosphoric acid in this manure. The extreme difference between any two of these determinations was 0·31 per cent of phosphoric acid." The extreme closeness of this result with that arrived at by Professor Jamieson is, of course, evident: adopting it for comparison, with No. 1 result, there is a difference of 2·74, equal to 6 per cent of phosphate of lime, or more than one-third of the total phosphate present. The following remedies are proposed for the consideration of chemists, and it may be mentioned here that no less than fourteen chemists, whose names are given in the appendix, have signified their willingness to perform analyses on the plan here suggested.

After much consideration, I venture to propose—(1) Uniform methods of analysis known to give strictly accurate results, viz., the Molybdenum process, checked and confirmed by the Uranium process. (2) Uniform methods of expressing results, viz., the percentage of the element phosphorus in the three forms of (*a*) soluble phosphate of lime, (*b*) insoluble phosphate of lime, (*c*) phosphates of iron and alumina. (3) Reference, in need, to a competent chemist, whose engagements do not preclude his performing the analysis personally, who will state the number of estimations made, the methods employed, and the extreme variation.

Professor Jamieson proceeds to describe and defend the processes of analyses recommended, and he especially commends the uranium process, inasmuch as by it the phosphates of iron and alumina can be separated, and their presence and proportion exhibited—a matter of considerable importance, as, if not altogether useless, their manuring value is much less than phosphates from other sources.

As regards the second proposition as to expression of results, Professor Jamieson points out the importance of terms which can be understood by the unscientific, and the confusion that now prevails owing to different expressions for the same thing. By stating the phosphate in terms of its essential element, "phosphorous," the utmost possible simplicity is reached; and there is the other advantage, that by the simple factor of 5 the quantity is converted into the other extreme of phosphate of lime.

The following example is given:

Phosphorous (as soluble phosphate of lime), 5·51
Phosphorous (as insoluble phosphate of lime), 0·49
} equal 30·0 phosphate of lime.

Phosphorons (as phosphate of iron and alumina) 0·61.

It is also stated that the same principle might be adopted as regards determinations of nitrogen, potassium, and other elements of plant food.

Professor Jamieson appeals to farmers through their self-interest; and if the evidence produced is unassailable, and it is a fact that, owing to faulty methods of analysis, from two to three per cent more phosphate is shown than actually exists, and consequently paid for, then all that is necessary is to publish the fact to insure attention; and farmers have the matter in their own hands if they follow out the suggestions now offered, which are—

1. Each to ask his manure merchant to state the *guaranteed* percentage of *phophorous* present as phosphate of lime (soluble or insoluble).

2. To send the manure for analysis to a chemist *known to use the above method.*

Manure merchants are asked to aid the reform by instructing their chemist to analyse by the molybdenum and uranium methods, and report the phosphates or *phosphorous* in the three forms of (1) soluble and (2) insoluble phosphate of lime, and (3) phosphates of iron and alumina.

The following chemists approve of the proposals in the pamphlet, and are willing to perform analyses on the principles indicated thereon:

London—Professor Church, F.I.C., Royston House, Kew; Otto Helmer, F.I.C., 11, Billiter-square, E.C.; C. T. Kingzett, F.I.C., 17, Lansdowne-road, Tottenham, N. *Norwich*—Frs. Sutton, F.I.C., London-street. *Cirencester*—Professor Kinch, F.I.C., Royal College of Agriculture; Professor Prevost, F.I.C., Royal College of Agriculture. *Salisbury*—Professor Munro, College of Agriculture, Downton.] *Liverpool*—A. M. Graham, F.I.C., 3, Union-chambers, Union-street; Dr. J. Campbell Brown, F.I.C., University College. *Leeds*—Thomas Fairley, F.I.C., 16, East-parade. *Dublin*—Dr. Cameron, F.I.C., 15, Pembroke-road. *Glasgow*—R. Tatlock, F.I.C., 138, Bath-street; Dr. Milne, F.I.C., 180, West Regent-street. *Aberdeen*—T. Jamieson, F.I.C., 140, Union-street.—*Field.*

REPORTS OF THE COLONIAL BOTANICAL GARDENS.

The reports of the several Colonial Botanical Gardens which we receive from time to time, though, of course, largely occupied with administrative details that have little interest for the home reader unfamiliar with the peculiar

local circumstances of each particular case, frequently contain some matter of general interest. It is pleasant to see how in the older colonies the value and importance of such institutions is in general fairly recognised.

Such institutions have several distinct but mutually connected functions to fulfil. They are, or ought to be, great educational institutions wherein the student should find the means of studying the vegetation of the country, and of selected representatives of the flora of other countries, such as it may be possible to cultivate.

When we speak of educational institutions we do not limit the term to pure science, the demand for which, and the means for which must, as a rule, both be small in the colonies; but we would include also the practical applications of botany, such as the merchant and the planter would appreciate, and the horticultural and agricultural element which contributes not only to the food and physical welfare of the population, but to the culture and refined enjoyment of the people. These latter matters, though less capable of direct estimation, are, in the long run, fully as important to the general welfare of a country as those the practical advantages of which are more immediately apparent. Science looks to these establishments for aid in the discovery, determination and distribution of the native plants, for investigation as to the conditions, climatal and otherwise, under which their cultivation can be carried on—in fact, for the elucidation of all matters connected with the flora of the country, its geographical distribution, its natural history, and its use for horticultural or economic purposes. Services such as these are available for the whole civilised world, and to render them is, in a degree, to repay the advantages and benefits conferred by our common civilisation.

Of more restricted but still vast importance are the experiments which should always be carried out in such gardens—experiments having for their object the determination of what plants can be profitably introduced into cultivation with a view to increase, not only the local resources and wealth of the country, but the advantage of the world at large. We need only specify what has been done in the case of the Cinchona, and of the Tea-plant in India, to illustrate our meaning.

In the third place, these gardens should contribute to the welfare and gratification of the residents. This may be done by keeping the gardens in such condition as to be agreeable and sightly at all times; they should furnish evidences of taste and culture, such as cannot fail to be beneficial, and which go far in the eyes of the public to justify the expenditure. Public appreciation is likely to be roused by the sight of a well-organised, well-maintained establishment, which, while contributing to the recreation of the people, and cultivating their sense of beauty, has, at the same time, a business-like aspect, which appeals more directly to their sense of what is fitting.

We have before us as we write recent reports of three of these institutions, and if we advert to them only on this occasion, it is with no intention of disparaging the others. Who could do so who remembers the splendid services rendered in India, in Melbourne, in Sydney, and elsewhere, by botanic gardens and their Directors?

Dr. Schomburgk's report on the Botanic Garden at Adelaide gives a vivid picture of the difficulties of maintaining a garden where great extremes of temperature and humidity occur. In June and July the temperature on several occasions was as low as 29°, the frost proving very prejudicial to the tropical Figs and other plants. In January, on the other hand, the weather was of a torrid character—112° in the shade and 180° in the sun! not so much below boiling point—while the rainfall for the entire year was only a little over 18 inches. A large part of Dr. Schomburgk's report is occupied with details of the trials of varieties of Wheat and fodder plants. Certain Millets withstood the drought well, and prove excellent for their purpose. The Cytisus proliferous also is shown to be highly valuable as a forage plant in South Australia. Vitis californica is mentioned as valuable as resisting the Phylloxera, and, therefore, as likely to be useful as a stock for grafting other Vines upon. Flower farming for the purpose of the manufacture of perfumes is alluded to as eminently suitable for South Australia, though at present not much practised. The Museum of Economic Botany is said to be highly appreciated from the way in which the utilitarian side of botanical and horticultural pursuits is brought home to the public.

In this connection it is impossible to overlook the zeal and energy shown by Baron Mueller at Melbourne for the last quarter of a century, not only in scientifically investigating the native flora, but also in seizing every opportunity of showing by practical experiment the commercial and economic value of plants.

The terrestrial paradise at Peradeniya has, under the care of Dr. Trimen, been redeemed from the condition of jungle to which, from want of thinning, it was approximating. The situation of this garden, and of the others associated with it, is such that the introduction of Cinchonas has been carried to such an extent that State aid is no longer needed there to distribute this valuable tree, the best varieties being now in general cultivation, thus leaving space for trials with drugs, dyes, and other products, which need to be tried. Mr. Ward's researches into the Coffee disease (Hemileia) have been successful in unravelling the whole history of the pest, and of showing the necessity for co-operation and united action on the part of the planters in the endeavour to stamp out, or at least restrict, the disease.

Ceylon seems to be favourably placed for the introduction of the various "rubber plants," especially the species of Landolphia which promise to be of such vast commercial importance in the supply of caoutchouc. We cannot now mention more as to the useful work carried on in Ceylon, but we note the complaint of the Director that he is called upon to sell Ferns, Orchids, &c., for conveyance to England and elsewhere at a direct pecuniary loss to the garden; and, what is worse, at a sacrifice of time and energy which should be devoted to more important and relevant matters.

This leads us to speak of the third report on our table, that of the Botanic Gardens at Cape Town under the management of Mr. McOwan, a highly competent botanist. The condition of the garden is, as some of our own correspondents have informed us, and as is substantiated in the report before us, far from satisfactory. Mr. McOwan complains bitterly of deficient water supply, without which it is obvious no garden can exist. Eucalyptus and other useful trees have, however, been largely distributed, and a useful hint is given as to the possibility of distilling spirit from sugar Sorghum, in the event of the introduction of the Phylloxera to the Cape, and the consequent loss to the wine growers. But what strikes us with nothing less than disgust is the fact that the authorities have so little appreciation of what duties a botanic garden should perform, and what the work of its Director should be, that we find the State neglecting its proper business and undertaking that of the nurseryman. The receipts and expenditure of the garden are somewhere about £2,000 annually. Of the receipts, £500 are supplied by Government, £189 by private subscriptions, leaving £1,300 or so to be raised from the sale of plants and seeds! So that here we have a highly talented Director, capable of doing excellent public service, reduced to the condition of a salesman, and the garden turned into a nursery establishment, hard pressed in competition with the local nurserymen, who complain on their side of the illegitimate interference of Government with their lawful calling. This is altogether a most humiliating state of things, and the more to be deplored from the peculiar opportunities of furthering botany and horticulture, scientific and economy, which a properly organised and equipped establishment at the Cape has. At present, it seems, the Botanic Garden does not and cannot mind its own business, while its energies are vainly frittered in the attempt to do what it has no right to meddle with.—*Gardeners' Chronicle.*

LANDRE AND GLINDERMAN, of Amsterdam, reporting on American goods, say:—*Coffee-mills* are now disposed of in considerable numbers, and give general satisfaction. *Coffee hulling and polishing machines.*—A long-felt want of improved machines for hulling and polishing coffee has lately been supplied by the introduction here and at Rotterdam of the "Santa Cruz Coffee Huller," manufactured at Lynn, Mass. They are now in operation, and the indications are that they will give complete satisfaction.—*United States Consular Report.*

OLIVE GROWING IN AUSTRALIA.

Since the impost of a protective duty of 6d. per gallon on olive oil, the Australian Oil Factory in Melbourne, Victoria, offers 10s. per cwt. for olives. An ordinary yield from an olive tree in bearing is from 4 to 6 cwt. An olive field is not too thickly planted which contains 100 trees; and 100 trees per acre, yielding even 4 cwt. or £2 per tree, gives the handsome gross return of £200 per acre. In South Australia the growing of olives and the pressing of the oil have become firmly established, and the plantations are increasing annually. Those who are engaged in olive culture assert that nothing they have yet tried pays them so well. A South Australian olive grower, Mr. Barnard, in a recent paper read before the Adelaide branch of the Farmers' Association, pointed out that the olive claimed attention at the hands of the farmer as one of the most remunerative products that he could possibly adopt as an adjunct to his other agricultural operations. His paper, summarised, showed—1st. That the olive is a tree that does not take up much room. 2nd. That it is a great protection from the hot and blighting winds, and affords a grateful shade in summer, and shelter in winter to cattle. 3rd. That it does not require a great deal of pruning and attention. 4th. That the wood is hard and close-grained, and very useful for all sorts of purposes. 5th. That it can be put in the form of small, six-inch rooted seedlings, only costing a mere trifle per hundred, by running a common plough twice or thrice along the same furrow in order to get sufficient depth, and placing them at intervals before turning a fresh furrow. 6th. That the oilcake, which by arrangement, can be returned by the oil manufacturer for a trifle, is most fattening food for pigs and poultry. 7th. That it is comparatively more profitable to the farmer than to those who are entirely confined to and dependent upon plantations, from the notable fact that they bear much more heavily in the single rows, as round the fence of a wheat paddock, where the light and sun can get round them, than in the close olive groves.

A special reporter, while on a tour in South Australia, inspected various olive plantations in that colony. At Mr. Davenport's place, near Adelaide, he found that 150 gallons of oil had been made from the year's crop, which amounted to 75 cwt. of olives. One cwt. of fruit produced 2 gallons of oil. The yield of Mr. Davenport's olive trees varied, according to age and size, from one to 20 gallons, but one very old and celebrated tree had been known to give up to 55 gallons. The heaviest expense connected with the industry was the picking, which cost from 2s. to 3s. per cwt. This was done by women and children.—*Melbourne Leader.*

[Amongst the special attractions of the Melbourne Exhibition were the beautiful olive oil trophies shewn by Mr. Davenport.—Ed.]

CINCHONA.

Some rather disjointed and fragmentary notes upon certain points in the culture and preparation of Cinchona Bark to which our attention has been specially directed, and for these we are chiefly indebted to Mr. Charles G. Warnford Lock, F.L.S., editor of Spon's new Encyclopædia. Propagation by "Layering," a method by which a far greater number and more rapid succession of Cinchona plants may be propagated than by the ordinary system of cutting, is that known as "layering" This operation consists in bending the branches of the plants into the soil, and cutting them half through at the bend; the object of this is to cause roots to spring from the cut portion of the branch, which is placed in the soil for that purpose. The juice of the plant escapes so rapidly from the cut as to induce decay, unless at once absorbed; this end is attained by placing a piece of thoroughly dried brick in the slit formed by detaching the tongue. The latter is then kept down, if necessary, by means of the peg. When it would be inconvenient to bring the branch down to the soil, the latter may be raised in boxes. The best season for layering is during the rains. When well rooted, say in 3—4 months, the layers are separated from the parent plant, and removed to glazed frames, where they are placed about 6 in. apart in good soil. Here they become established as "stock plants," and yield a constant succession of cuttings. In taking these, whole shoots must not be removed, but a few buds must be left to provide new shoots. Cuttings from stock plants are treated in the same way as any others. [What we saw of layering on the Nilgiris and in British Sikkim produced the impression that this is about the most difficult mode of propagating Cinchonas.—Ed.]

Drying.—In our last we gave some particulars of an apparatus manufactured by Messrs. J. Gordon & Co., for artificially drying the bark. Since then we learn that Mr. Kinmond has patented a machine for the purpose which answers well in practice both for tea and cinchona, and one of them has been supplied to the Neilgherry Tea and Cinchona Co., of which Mr. Teare is the resident manager. These machines are manufactured for the patentee, by Messrs. Robey & Co., of Lincoln. Experts are of opinion that the bark should not be subjected to artificial heat more than 12 to 15 degrees above that of the outer air or its chemical qualities will be prejudicially effected.

Colisaya Verde.—Mr. Holmes' article in our February number, describing the cultivated Bolivian variety, has induced a very active demand for the seeds, and we may mention that Messrs. T Christy & Co. are expecting a fresh supply in a month or six weeks. From an estate in the Wynaad, to which a small quantity of the seed was sent in February last, we learn that it germinated most successfully in about 10 days after being sown. The manager calculated that there were about 60,000 seeds to the oz.—*Planters' Gazette.*

THE SAGO PALM IN BORNEO.

Amongst the papers issued by the gentlemen connected with the Charter for North Borneo is an interesting one on Sago Planting.

It is stated therein that the Sago Palm is indigenous in Borneo, and grows to perfection there, nearly seven-eighths of the Sago brought into the European markets being produced in the island.

The Palm appears to be a most prolific plant, three trees yielding more food than an acre of wheat, and six trees more than an acre of potatoes. A single tree will give 600 lb. of food, sufficient to support a grown up person for a year.

The cultivation at present is entirely in the hands of the natives. But Mr. W. M. Crocker, a gentleman of long local experience, recommends that in British North Borneo an experiment should be made by the Directors of the Company of planting this Palm on a large scale.

As a preliminary he gives an estimate of the probable cost of and profits from a plantation of 2,000 acres, of which the following is a summary:—

On the 2,000 acres 100,000 trees would be planted. The total cost at the end of ten years from the first start, including interest is put at £17,280.

The plantation would then be ready to produce 30,000 trees annually. And it is calculated that for a yearly outlay of £6,950 there would be a net return of £22,500, leaving a yearly profit of £15,550.

Nothing is charged for the land, as the Directors of the North Borneo Company have it at their own disposal.

There can be no doubt that the statements made by Mr. Crocker, which, it may be added, are said by the *Sarawak Gazette* to be well within the ascertained facts, will receive the close attention of those who are undertaking the responsibility of acting as pioneers of planting in North Borneo. And it may well be that in the cultivation of the Sago Palm there may be found a most useful and lucrative adjunct to the growing of other products. But it is clear that the length of time required for a return would quite prevent it being made a staple, at least by the earlier planters. Man must live, and he cannot live on future profits, especially if those profits be based solely on *estimates*, as in this case.

In writing thus we must not be supposed to be casting any—the least reflection on Mr. Crocker's figures. These are, doubtless, fairly and moderately deduced from facts well within his knowledge. But to illustrate our meaning we may mention the case of the early Cocoa Nut planters in Ceylon. The cultivation of that Palm some forty years ago, as of the Sago Palm now in Borneo, was entirely

in the hands of natives. The palm trees so cultivated bore, and they still bear, several hundred nuts yearly.* Estimates were made, and it was proved beyond question, that any one who would wait twenty years could make his fortune by planting a cocoa nut estate. Many estates were planted, and some have given a fair return for the money sunk, but no fortunes have been made. The simple fact is, that with all care and attention, the trees thus planted out on estates do not bear at all as those planted about native dwellings. In place of gathering a hundred nuts per tree yearly, the crops dwindle down to a miserable four or five; or, as in one case of which we have heard, to two!

We should be glad to learn a little more as to the system on which the cultivation of the Sago Palm is at present carried on in Sarawak, whence it seems that 7,000 tons of sago flour are even now exported yearly, and where the cultivation and manufacture already afford a steady industry to some thousands of people.—*Planters' Gazette.*

[Cassava growing has already been overdone in the Straits and there is danger of the same result in regard to Sago, unless the article can be produced cheaply enough to be used as food for calves.—ED.]

MR. SIMMONDS, COMPILER OF THE BOOK ON "TROPICAL AGRICULTURE," IN CORRECTION.

To the Editor of the "Tropical Agriculturist."

Crystal Palace, Sydenham, March 31st, 1882.

DEAR SIR,—In a letter in the March number of the *Tropical Agriculturist*, p. 817, from Mr. H. Cottam, I notice a serious charge, which I trust, you will allow me to reply to. Mr. Cottam states that in my "wonderful book on tropical agriculture the outturn of coffee of the world is by a misprint given at one million instead of ten million cwt." I immediately turned to my book and could not trace this error.

My words are:—"Taking the production at present at 13,000,000 (thirteen million hundredweights) which is certainly within the mark." This was, of course, to a great degree an estimate. But then I gave subsequently the actual statistics of production for the year 1875 made up from official returns, amounting to 11,338,530 cwt. (eleven millions three hundred and thirty-eight thousand five hundred and thirty hundredweights). My book was published in 1877, and yet the figures agree tolerably well with your estimate in your Handbook printed several years afterwards "of 11 million cwt. as the quantity exported, the producing countries consuming three millions more."

I am sorry to find from your editorial note that "my book has a number of gross errors." Covering as it does so large a field of observation and reasoning in many instances on questionable data, I could not possibly be always so well-informed as those locally conversant, but I took the greatest trouble and pains in getting at my facts, and endeavoured to lay a foundation on which others, more experienced, could estimate and correct the opinions and statements I advanced.—Your obdt. servant, P. L. SIMMONDS.

[We regret very much the long delay which has occurred in publishing the above letter, but the fact is we had mislaid the particular copy of Mr. Simmonds' useful and elaborate compendium on "Tropical Agriculture," on the margin of which we had made notes of some gross errors occurring in the pages referring to coffee; we do not blame Mr. Simmonds for these, for it would be a marvel indeed, if dealing with so wide a subject, he could have secured accuracy in reference to every country and product treated of in his book. We do not know where Mr. Cottam got the million cwt. he referred to, but here are the passages noted by us which we have no doubt Mr. Simmonds will correct when the next edition of his volume is called for:—Page 34, the export of coffee from Java in 1869 is given at 3,299,000 cwt., then follows:—"the crops were defective from 1864 to 1867. *The export has occasionally reached* 170,000,000 *lb.*" This is ridiculous —170 millions lb. equalling 1½ million cwt.; while, as Mr. Simmonds shows in two lines above, the export has occasionally reached over 3 millions. On the next page, 35, there is a statement about 126 millions of coffee trees *in bearing* in Sumatra giving about 100,000 cwt. of crop (in 1872), or 1 cwt. per acre, and not much more in 1874, which we regard as absurd: probably the figures represent the export and not the yield. Leaf-disease had not then affected coffee in that quarter. On page 57, Mr. Simmonds will find some blundering under Africa where the eastern and western coasts and islands are put down for a production of 2 millions lb., while St. Thomas alone is credited with 1⅔ million of this. On page 59, it is said Liberian coffee will enable planters to pursue their calling "at elevations above the fever line"; quite the contrary being the case. We have marked "absurd" opposite the statement on page 63, that in 1844, 20 millions sterling were invested in coffee estates in Jamaica. We have queried and we doubt the statement on page 64 that Cuba imports large quantities of coffee from Porto Rico; also that "the coffee plant is a native of this continent," meaning America, given on page 65. The information about coffee exports from Brazil on pages 71-2, is given in a very misleading way.—The foregoing is simply a transcript of our pencilled marginal notes made in 1878. Many years before that, we had given in our Handbooks estimates of the total production and consumption of coffee. But, after all, as we have said, Simmonds' is a very useful book, and, as a proof of our interest in it, we may say that more copies have probably been disseminated through our agency in Ceylon than in any other tropical colony. But a serious complaint against the compiler remains,—that of wholesale appropriation without acknowledgment. For instance, the larger portion of an Essay on Tea cultivation, written for the Ceylon *Observer*, without a single word as to the source whence it was derived. That is only a specimen.—ED.]

INDIA:—CROP AND WEATHER REPORT.

For the Week Ending the 5th September 1882.

General Remarks.—Good rain has fallen throughout the Madras Presidency; prospects of standing crops are good, and harvesting has commenced in a few places. In Coorg the monsoon has set in again; rice and ragi crops are doing well. In the Mysore State, in the Nizam's Territories, and the Berars there has been light rain, except in Hyderabad where it has been heavier; standing crops are in good condition and prospects are favourable. In the Bombay Presidency good rain has fallen in all districts except Guzerat, and has been beneficial to standing crops; parts of the Guzerat division are in need of more rain; locusts are reported from a few places. In the Central Provinces the kharif crops have benefited by the recent break in the rains and are promising well; weeding operations are in progress and occasional showers are occurring.

In Central India and Rajputana rain has been reported from every State, except Sirohi, Jeypore, and the British district of Ajmere, and prospects are favourable everywhere except in Sirohi. Rain has also been general throughout the Punjab, except in Hissar and Peshawar. The North-Western Provinces and Oudh have had more or less good rain in all districts; early crops are being cut, and prospects of all other crops are good; more rain is now wanted in part of Lucknow only. In Bengal rain in varying quantities has fallen in all districts; prospects of the winter rice crops have improved, jute and sugarcane

* It is the rarest thing, if possible, to see a coconut palm which in one year has perfected 200 fruits. Forty is a high average.—ED.

are in satisfactory condition, and the autumn harvest is progressing, with promise of a fair average outturn; a little more rain would help the transplanting of the winter rice crop in some places. In Assam the transplantation of the winter and the reaping of the early autumn crops are progressing; rain has been general; tea and sugarcane are doing well.

In British Burma good rains has fallen everywhere except in two districts, where it has been light; agricultural operations are, on the whole, progressing satisfactorily, except in parts of Prome and Tharrawaddy.

The general fall in the barometer noticed last week was succeeded by a rise which, beginning in Western India, spread over all parts of the country, and was again followed by a steady fall all over India.

Madras.—General prospects good.

Assam (Cachar).—Weather warm; transplanting of sali and reaping of dumahi and murali crops continues; tea doing well; common rice 21$\frac{5}{16}$ seers per rupee; no more cholera reported.

Mysore and Coorg.—Rain continue to fall throughout the Mysore State in Tumkur 2·29, the Hassan 2·52 Shimoga 3·30, Kadur ·43; crops in good condition; prospects favourable; prices compare favourably—in Bangalore ragi 26½, horse-gram 40¾, in Mysore ragi 25½, horse-gram 30¾, in Shimoga ragi 19 to 39; gram 25 to 40 seers per rupee.

FRUIT CROPS IN ENGLAND.—Those who recommend the British farmer to take to fruit growing for market as a partial remedy for agricultural depression would do well to scan previously the annual records of the Fruit Crops given in our columns before they counsel the locking up of capital in fruit culture. We do not now care to say any thing about foreign competiton, the difficulties of carriage, of realising a satisfactory market price—the glut at one time, the deficiency at another—but we do advise the would-be fruit-grower on a large scale to cast an eye over the records of the last ten or a dozen years, and see if they are at all encouraging. Beginning with 1870—for ten years is quite long enough for our purpose now—we find in 1870 that fruit crops of all kinds were generally abundant; in 1871 they were scanty and late; in 1872 there was universal failure. In 1873 the crop was reported under average. In 1874 the yield was over average, so it was in 1875; but in 1876, 1877, 1878, 1879, 1880—five years in succession—a failure was recorded. In 1881 the crop was a fair average; and now in 1882 we have another general deficiency to record. Taking the whole breadth and thleng of the British Isles, there were only three out of thirteen years in which the apple crop was abundant, only one wherein it was fair, and in all the rest deficient. This is not a tempting prospect.—*Gardeners' Chronicle.*

A WONDERFUL GRASS.—The *soya hispada* grass is, if all that is claimed for it be true, one that should be introduced into Australia without delay. The uses it can be put to are varied and numerous. The *soya* is a native of Central Asia, more particularly of the eastern portion of the continent. It flourishes in China and Japan, and has found its way to Hungary. It is also largely cultivated in Syria and Dalmatia. The grass, if soaked in water, becomes a delicious kind of lentil. Planted in a dark place, sheltered from the sun's action, the long white stalks sprout up into a kind of celery-endive. The seeds when ground and pressed yield a valuable vegetable oil; the refuse can then be made into oil cake for fattening cattle. Treated in another fashion, the juice can be manufactured into a sauce, which is much esteemed by Chinese epicures. When dry and cut up it is a valuable feed for horses. One would almost fancy that the above were sufficient uses for a plant to be put to, but the *soya* possesses still more valuable properties. The seed, or grain, when dried, roasted, and ground, forms an excellent substitute for coffee. Its stalks are woven into a coarse kind of cloth, and mats, etc., are also made of it; and last, but not least, it has fattening properties of no mean order. We can only say in conclusion that if the *soya hispada* is what home journals represent it to be, its introduction into this colony will cause the wail of "feed scarce" to become a thing of the past —*Planter and Farmer* [Queensland.]

PROPOSED CULTIVATION OF CINCHONAS IN THE UNITED STATES.—In consequence of the resolution recently passed by the House of Representatives recommending that the possibility of acclimatizing some species of *Cinchona* in the United States should be inquired into, a report has been made by the Minister of Agriculture, in which he expresses an opinion that some of the species, especially *C. succirubra*, would live in Southern Florida, but suggesting as most promising for the establishment of an experimental plantation the higher lands in Southern California. It may be mentioned, however, that experiments in cinchona cultivation were made in the region referred to a few years ago and were uniformly unsuccessful.—*Pharmaceutical Journal.*

ROSES FROM CUTTINGS.—I was at Wood and Ingram's nursery a few days ago, where, amongst other things of an interesting character shown me, was a little frame in the propagating house filled with rose-cuttings rooting in a bed of cocoa-nut fibre. The cuttings had been taken from plants grown under glass, the shoots of which were just getting firm. Several were pulled up indiscriminately, and each had formed delicate little roots half an inch or so long, just in the right condition for potting, or, as was remarked, planting out at once in the open border, judiciously sheltering and shading for a time. There was no heat in the house beyond sun heat, and of course the fibre being partly decomposed, there was no heat there. The majority of cuttings which fail are killed by the watering pot; but cuttings in such substances as cocoa-nut fibre and sawdust require but little water. As the material retains moisture, there is no occasion to be always watering. The middle or end of July is a good time to strike rose-cuttings in a frame full of cocoa-nut fibre, or old moist sawdust from hard wood, not deal. Take the shoots that are getting firm, shade in bright weather, and dew the leaves over occasionally. As soon as the roots are formed, the little plants must be taken from the propagating bed and potted off or planted in good earth, with a frame, over them. Many things strike in some non-conducting material—such as cocoa-nut fibre, old tan, or sawdust—better than in sand, that one has to be constantly watching, for fear it should get too wet or too dry.—E. H.—*Field.*

PETROLEUM AS AN INSECTICIDE.—After two years' experience I can speak very strongly in favour of petroleum (erroneously called paraffin) as an insecticide. For that worst of all pests, mealy-bug, on Gardenias and Stephanotis it is first-rate; and it is equally fatal to red-spider, thrips, and brown scale. I do not know who first made known its value for this purpose [Mr. D. Thomson], but I for one am greatly indebted to him. I use one-twelfth part of a pint to one gallon of water, and as often as I find any insects, whether it be once a month or twice a week. The most important point is the thorough mixture of the oil and water. I know of only one method by which it can be performed, and those who think it too troublesome had better leave petroleum alone and try Hughes' Fir-tree Oil, which is a capital thing, mixing easily with water, and is not unpleasant in the using; but as the quantity required for one gallon of water costs eighteenpence, while of petroleum the quantity required for one gallon of water costs half a farthing, we use petroleum. I put the oil and water in a vessel, and fill the syringe, then force it back into the vessel, repeating this action a dozen times or more before using any on the plants; afterwards each alternate syringeful is forced back into the can. It does not injure the roots or blooms apparently in the slightest degree, in fact, I am not quite sure that it does not benefit them. I enclose you a few specimens from plants that have been treated in the way I describe for the last two years (indeed, the last application was made four days ago), that you may see whether I am justified in saying so much. If so, I think it a duty to help to make known such a boon. I do not recommend it for such tender foliaged plants as Coleus or Cucumbers, and I think in the case of Gardenias and Stephanotis it is best used on a dull day or in the evening, when the sun's rays are not so powerful. I ought perhaps to mention that except on the days when the petroleum is used, the plants are syringed daily with clear rain-water. If any one has tried petroleum in this way for mealy-bug on Vines, I should be glad if he would kindly give us the benefit of his experience, as I have not so tried it.—G. DUFFIELD, Winchmore Hill.—*Gardeners' Chronicle.*

MARKET RATES FOR OLD AND NEW PRODUCTS.

(London Price List, August 31st, 1882.)

IMPORTED FROM MALABAR COAST, COCHIN, CEYLON, MADRAS, &c.	QUALITY.	QUOTATIONS.

BRITISH SETTLEMENT IN BURMA:

PLANTING PROSPECTS.

To residents in Ceylon much interest has always attached to the country which lies opposite us on the Bay of Bengal. Ethnically the energetic Indo-Mongolian race which inhabits Burma differs essentially from both the Sinhalese and Tamils, but the religious tie of Buddhism binds the Sinhalese, at least, to the Burmese. As our readers are aware, the Amarapura priests of Ceylon are so called, because men of what were deemed an inferior caste were driven by the bigotted caste prejudices of the Sinhalese priests to resort to Burma for ordination, so originating "the Amarapura sect" as a protest against what is said to be as foreign to pure Buddhism as it is abhorrent to the spirit of true Christianity. Like the rest of the Buddhist world, Burma recognizes Ceylon as the central home of Buddhism because it holds the much venerated dental relic of the great teacher of Nirwana and also because the Burman code is believed to have been brought from Ceylon by Buddhaghosa. Burma is a land of monasteries (in which every Burman is expected to spend a portion of his life), and the "monks," unlike their lazy confrères in Ceylon, are really earnest and industrious in the work of education, which is, as yet, largely in their hands. The laity, too, are industrious cultivators, especially of the great staple rice. Taking the whole of Burma, British and independent, we get an area of nearly 300,000 square miles, of which about 85,000 are under British rule, with 3½ millions of acres cultivated out of about 60 millions cultivable. It is as if we held the Delta of the Nile and all lower Egypt and were waiting until the unbearable insolence and aggressiveness of our neighbours compelled us to annex Upper Egypt. But Pegu is even more a land of rivers and tidal creeks, of deltas, floods and fertile mud-flats, than Lower Egypt, and the British, with so much to do in the region they hold, are only too anxious to postpone the inevitable in the case of Upper Burma. That portion of the Burmese Empire which we annexed in 1826 long proved unprofitable in a revenue sense. But with the annexation of Pegu in 1852 commenced a career of prosperity and progress such as few portions of the world, even under British rule in its best form, have shewn. The population has far more than doubled, the increase in the past 8½ years being no less than 36 per cent, while in 10 years the commerce has risen from about seven and three-quarter millions sterling to over eighteen. Rice is the overshadowing staple of this trade, the value of the portion exported last year constituting one-third of the whole value of the trade or nearly six millions sterling. Besides land revenue paid direct by farmers whose holdings average five acres, the export duty on rice is about 14 per cent of its value. But the returns are so good that the people are well-to-do, spending liberally on monasteries, shows and theatricals and spending an average of £12 per head on imported goods, largely jewellery. We are speaking exclusively of British Burma, of course, for the contrast across the border, where no man can call possessions or life his own if he incurs the displeasure of corrupt officials and a tyrant king, is as marked as that between the brightest day and the darkest night. The last census shewed that about a quarter of a million, that is one-eighth of the total population of independent (and anarchical) Burma had been attracted by British rule and liberal laws as administered by gentlemen whose present head as Chief Commissioner is Mr. Bernard, a nephew of the late Lord Lawrence, and a man and administrator of the same stamp. Mr. Bernard and his staff of British officers, with their successors for some generations, have plenty of work cut out for them, in the improvement of territory equal to nearly four Ceylons (between 80,000 and 90,000 square miles of area), of which the vast proportion is still uncultivated, although a full million of acres have been added to the crop-bearing land in the past ten years. Teak timber is the second staple in the trade of Burma and, in order best to utilize the timber and the grain, large imports of machinery have been made in the shape of saw-mills, rice-husking apparatus, &c. The revenue is large and increasing, and under the recently adopted system of assigning to the various provinces of the Indian Empire large proportions of the money collected, within their bounds, for provincial purposes, British Burma is likely in the future to outstrip the past in the path of progress. A canal has been cut to join two great waterways, and some important sections of railway have been constructed. But the great want to be supplied is that of ordinary roads, which from the nature of the country must be raised above flood level. The estimate for such roads is £700 per mile and considering the high cost of labor in Burma, it does not seem as if roads made at such a figure can be anything like those for which in Ceylon we now pay at the rate of £2,500 a mile. Of course there is a great difference between an abrupt mountain system and a flat plain, even although the plain is liable to periodical flooding. There are nearly 60,000 square miles of more or less fertile land still available in British Burma and these await labor and resident population. Labor is obtained from the same fields which supply Ceylon, those of Southern India; but in regard to Burma, even more than to Ceylon, apparently, the laborers do not go to settle, but to amass savings and return to "their country." As our readers too well know, there are many portions of the great Indian Empire over peopled, mouths being in excess of food, plentiful as that is in normal years. The remedy seems obvious: that the surplus should immigrate to such lands of promise as British Burma, where, good wages to begin with property in prospective and efficient protection of property and life await them. But exaggerated conservatism and an increasing nostalgia are the banes of the Hindu races and the plague of the race which wants to govern them for their good. And so, even with all the encouragement which the Provincial and Imperial Governments can afford, human beings die in millions or vegetate wretchedly, while untold wealth of food and all that renders life pleasant await them, if they would but have the moral courage to leave their ancestral homes and found new ones in better situations. The climate of British Burma is generally good, the exception here as all over India being the lower hill ranges. In Tavoy and Mergui there is abundance of mountainous country, where "the forest primeval" has not been desecrated by the axe and torch of the *ioomer* (or chenaer), and to such regions European life, capital, enterprize and industry are invited. Tea is indigenous in the forests, although the great Burmese dainty (next to putrid fish) of "pickled tea" is supposed to consist of the leaves of another plant, *Elæodendron Persicum*. As the rainfall ranges from 54 inches in the low-country to 245 in the high, there is plenty of scope for tea, coffee, cocoa, cardamoms (which like tea, are indigenous), nutmegs, and most tropical products. We refer our readers to the report of experiments made in Mergui by Dr. Helfer and more recently by the Deputy Commissioner, Capt. Butler. Of course, there would be the danger of disease in the case of coffee, and white ants and crickets seem as injurious to young cocoa plants as ever those pests have been in Ceylon. But, as Capt. Butler truly says, such obstacles can be fought and overcome. The labour

difficulty is a more serious one, but even that will not offer an insuperable obstacle to British enterprize and pluck and determination. The terms on which forest lands will be granted have appeared in our columns, and the record of Capt. Butler's experiments now, with the notice of what Dr. Helfer, in the face of all obstacles, accomplished in Mergui district, will shew what is possible to enterprize aided by capital and labour. The latitude of British Burma is more that of Jamaica than Ceylon, but the greater distance from the equator is not likely to constitute a serious objection. The climate and rainfall seem closely to resemble those of Ceylon, excepting that the period between October and December (inclusive) is even more a dry season than it is in our mountain region. Apart from the possibilities of agriculture, British Burma, with its slate formations alternating with granite, seems rich in minerals, from gold to iron, and from jade to rubies. So that the attractions are many-sided, and we cannot doubt that in the future even more than in the past the progress of Lower Burma will be onwards. *Upwards*, too, we might add, for recent events, which shew that the rulers of Upper Burma resemble the Bourbons in having learned nothing and forgotten nothing (that is forgotten nothing narrow and bad and vain and insolent), warn us that any day the British, however unwilling to annex more territory, may be compelled to extend their border until it marches with China, acting in the interests not merely of their own subjects and commerce but in those of outraged humanity.

REPORT ON EXPERIMENTAL CULTIVATION CARRIED ON BY CAPTAIN BUTLER, DEPUTY COMMISSIONER, MERGUI, DURING LAST YEAR.

In March 1881 a grant of R2,500 was sanctioned to meet the cost of planting out 10 acres of coffee and of making experiments on a limited scale of cocoa, nutmeg, pepper, and vanilla seeds, and plants were at once indented, for and operations commenced on the southern side of the forest plantation in clearing jungle, digging up roots, trenching the land, and preparing nurseries for the plants.

In reply to my indent for seed, I was informed it was then too late in the season to obtain any all last year's crop having been already sold or planted out. Messrs. D. Brandt & Co., of Singapore, sent me some plants instead:—

2,600 Liberian coffee plants,
600 cocoa or chocolate,
100 cardamoms,
300 pepper seeds planted in earth,
1 vanilla full-grown,

the cost of which, with freight, packing, and shipping charges, came to 274 dollars 75 cents or R634-4-0, and R150 more for the passage-money of the overseer to Singapore and back to bring up the plants; so that the total cost of plants landed in Mergui came to R784-4-0, leaving only a balance of R1,715-12-0 out of the grant for cultivation. Messrs. D. Brandt wrote subsequently offering to supply Liberian coffee seed at one cent per seed, equivalent to R25 per 1,000 seeds. I am inclined to think that it could be obtained even for less than that from Ceylon. For I was only charged R20 a bushel, which contains over 30,000 seeds, by a Ceylon firm for coffee-seed which I obtained through Messrs. King, Hamilton of Calcutta, but this turned out to be Arabian seed.

Results at the end of the year.

Coffee.—Of 2,600 Liberian coffee plants, which were all planted out in nurseries on the upper land under the shade of large forest trees, over 1,200, that is, nearly one-half, are doing well, being strong and healthy and making vigorous growth, throwing out large leaves from nine inches to one foot long, like a Portuguese laurel, and have already made over two feet of growth in the year, and there is therefore every prospect of the experiment being a complete success. The remaining 1,400 plants were more or less sickly from having got their roots damaged in the boxes in transit, and in consequence were afterwards unable to get their tap-roots well down into the ground, or to make any growth. On the approach of the hot weather they showed symptoms of drying up, their leaves began to fall. In January I removed them down to the banks of the creek, where the moisture in the soil from propinquity to water caused them to revive, though they were unable to make any growth; they are beginning to throw out fresh leaves, and will, I have every hope, pick up and become strong healthy plants by the end of the coming rains. The first supply of seed I obtained from Ceylon in November turned out a complete failure; not a single seed germinated. I am inclined to think it had been gathered too early, before it was fully ripe. I at once sent for a further supply, and this time with ample success. In every bed planted the seed germinated freely, and the young plants, about 8 to 10,000 in number, are strong and healthy in the nurseries awaiting for the rains to be planted out, but the plants appear to be Arabian instead of Liberian.

Cocoa or Chocolate.—This, I am sorry to say, has not been so successful as the coffee. In the first month after their arrival, 400 out of the 600 were carried off and destroyed by white ants and crickets, both of which pests swarm in the dense forest land round Mergui, and subsequently 140 more succumbed to their attacks, leaving us only 60 survivors. It is a consolation to know that this loss is not singular.

Ferguson, in their Hand-book on Ceylon, state:—"The failures with cocoa are, in our opinion, far more numerous than with either Liberian coffee, cinchona, or almost any other new product. White-ants and other enemies seem to make a dead set at the young plants, and if 12 per cent. survive of the first clearing, planters have considered themselves fortunate." Yet with this heavy percentage of failures cocoa seems advancing in Ceylon, and I see no reason to despair of its success here also, for it must be borne in mind that it succumbed to the ravages of insects, and not to soil or climate being unadapted to its growth.

Cardamoms.—Of the 100 plants sent more than three-fourths rotted in transit from too much damp on the journey. I subsequently found out that they were indigenous to the district growing wild in the Palow township, our revenue circle being called Palatike, or the cardamom circle, on account of its being found growing there. The seed is collected by the Karens and sold in the bazaar for Re1 a vise for spicing curries, but like most bulbous plants cannot easily be raised from seed; the plant propagates itself from shoots thrown out from the root.

Pepper.—The 300 pepper-seeds sent in earth never germinated; this also is to be found in many gardens in the suburbs of Mergui, climbing up to a great height on large trees, but it is not looked after or cared for as the natives seem to prefer the more pungent chilly and consequently its berries are generally carried off by birds or squirrels. If properly cultivated and attended to, it is said to be far more profitable than either tea or coffee, and it therefore seems curious why its cultivation has not been more extensively resorted to by European planters. I obtained 200 to 300 cuttings from the gardens in Mergui, and planted them at the roots of large forest trees, where they soon took root, established themselves, and are now growing vigorously.

Vanilla.—One hundred cuttings were ordered, but Messrs. D. Brandt & Co., sent instead one large full-grown plant, from which he said it would be far better for us to take as many cuttings as we re-

quired after arrival here than for him to sent small cuttings, which might get dried up or damaged in transit, and the result has proved the correctness of his advice, for upwards of 20 cuttings have already been taken from this single plant and planted at the foot of large forest trees without a single failure ; one cutting is already 25 feet high, another 20 feet, the rest from five feet to eight feet, but all doing well, looking strong and vigorous ; whereas two cuttings obtained by the Forest Department from Ceylon two years ago, have not grown an inch or thrown out a single shoot.

Nutmegs.—Some seed or nuts were obtained from Chinese gardens in Mergui from trees originally imported by Dr. Helfer. Only 12 plants were raised from over 100 seed nuts. This, I am inclined to think, was from the seed being planted too fresh, for when gathered from the tree the seed is then full of green sap, which, when placed in the ground, rapidly ferments and rots, but if the seeds were to be well dried in the sun before planting, better results would probably be obtained.

There are only about five full-grown trees in Mergui and as the seed nuts can be obtained from R1·8 to R2 a hundred, a further trial can be carried out next year without much expense. It is a delicate plant and requires both care and time to raise, and takes from six to nine years to come to full maturity ; it then amply repays one by its very bountiful returns. Each tree bears from 2,000 to 3,000 nuts, which at R1·8 per 100 would bring in R20 to R30 per tree ; and as they require no expense in curing, the fruit being merely dried in the sun and are then fit for market, ought to make it one of the most profitable of tropical garden products. They are extensively cultivated in the Straits Settlements, where the export in 1867 was 485,123 cwt. of nutmegs valued at £50,559 and 5,416 cwt. of mace valued at £7,354, which will show it is a cultivation well worthy of every endeavour to introduce. Last week, while walking round the forest plantation with Mr. Hill, Conservator of Forests, we were rather astonished to come across a quantity of fallen fruit under a tree, which on examination turned out to be wild nutmegs, the *Myristica fatua* or *tomentosa* of a longer shape and smaller.

Labour.—The amount spent under this head amounted to R1,510. For this sum 6½ acres of land have been cleared of jungle, and 3½ of this has been dug up, cleared of roots, and trenched, and 1½ planted out, the young plants raised from seed being still in nurseries waiting for the rains to be planted out, as to plant out in the hot weather would have killed the young seedlings This would seem rather a small area for the outlay, but it must be borne in mind that this includes building sheds, fencing the nurseries against the encroachment of deer, for both Sambhur, mouse, and hog-deer abound in the dense jungle round, clearing paths, planting and transplanting, watering during the hot weather. Operations were commenced just at the beginning of the rains, the most unfavourable season of the year to make clearings, for the sap is then well up in the wood, and the jungle cleared will not then burn easily and and require to be stacked ; the ground is then wet and heavy, and large forest trees and roots difficult to move or get rid of. Heavy showers throughout the rains more or less hamper the work, which ought, properly speaking, to be done in the fine weather.

However, taking all things into consideration, I think the results are not altogether unsatisfactory. All the plants raised from Ceylon seed, and half of the Liberian plants that were sickly and had to be removed to the lower ground, are still in nurseries, and if the original intention of planting out 10 acres with coffee is desired to be carried out, a further grant of R1,000 to R1,500 will be required for this year's operations to complete that extent. [A further grant of R2,500 was made to Captain Butler with a special recommendation to pursue the experiment in coffee.—ED.]

After writing the above we were favoured with the following figures for rainfall at Tavoy for three years, as supplied to a Ceylon planter by the Deputy Commissioner of Tavoy. From these it will be seen, that in Tavoy at least, October and November are just what they are in Ceylon, rainy months, and that the dry season is also coincident with our own, over the south-western portion of our mountain zone, extending from December to March, inclusive. Over the remaining eight months of the year, the rain is pretty well distributed, although the great bulk falls in the four months, June–September. In July of 1880 it will be seen very nearly 67 inches fell, and nearly 50 in August last year. The average for the three years is 208·65 inches, which, as well as the four rainless months, constitutes a pretty good tea climate as far as rainfall is concerned. In 1879, out of 221·25 inches, 163·29 fell in the four months June–September, leaving 57·96 for the rest of the year. In 1880, the result was worse, 168·44 for four months, leaving only 46·70. Still more unfavourable was the result of 1881, 160·27 for four months and only 29·41 for the other eight. But Darjiling shews a similar climate. Figures for temperature, however, are desiderated, although there can be little doubt that there is warmth enough and to spare in the hot season.

Rainfall in Tavoy for the past three years.

By a slip of the pen we yesterday represented the cultivable land reserve of British Burma at nearly 60,000 acres. For acres read square miles, representing an acreage of 38,400,000. And this reminds us of a fact mentioned in Mr. Bernard's Administration Report which may be quoted as an encouragement to our authorities in Ceylon to push forward a regular cadastral survey. The result of such a survey in British Burma has been to reveal so much more cultivated land than unscientific surveys had previously shewn that the land revenue, by this cause alone, was increased 22 per cent. The tax is about one to nine on gross produce, which accords with our Ceylon rate, only that here we tax only one article of produce, grain—leaving all else free. This very liberality has been quoted against our Government by wonderful political economists, who, to get rid of "a bread tax," proposed a land tax which would affect roots, fruits and vegetables as well as grain. No doubt a land-tax is a fair tax, *where it can be worked*, and where it stands in lieu of much other taxation. But Governments must consult possibility and expediency, as well as hard and fast equity, in taxation. Grain is taxed in Ceylon just on the principle that tea is taxed in Britain. Revenue is necessary to good government, and it is better to levy it from a few

articles of general use, than to spread taxation in a fashion equally vexatious and unproductive. The rice-growers of Burma are doubly taxed. They pay land tax and their produce is taxed when exported. But the benefits conferred on them are more than commensurate, if we look but at the wonderful decrease in crime. It is but rarely now that a young Burman engages in dacoity in order to prove his manhood. Happily Burma is free from those terrible curses of India, child marriages and child widowhoods. The people are able to marry early, however, and the natural increase of population is very rapid. What with this increase and the results of immigration from Foreign Burma and India, the cultivated area has increased in ten years from 2½ to 3½ millions of acres,—the increased breadth of cultivation being at the rate of 100,000 acres per annum. If the world's demand for rice goes on as it has done in the past decade, the next will shew a much greater annual increase in rice land, while we cannot doubt that the process of utilizing the bill forest lands will make good progress amongst the Burmans proper, while the rapidity with which the Karens have adopted, propagated and sustained the religion brought to them by missionaries from America, is without parallel since apostolic days.

NEW PRODUCTS IN CEYLON :—LOWCOUNTRY REPORT.

LIBERIAN COFFEE—COCOA—CARDAMON—WAXPALM—ORANGES—CEARA—RUBBER.

(July and August 1882, *in the Lowcountry East of Colombo.)*

Throughout July, and especially in its latter moiety, the rains were heavy and frequent for the most part, accompanied by strong wind. On the 29th we had the heaviest shower we have experienced since this estate was opened : it lasted for less than an hour, but it proved the inefficiency of the drainage system, that has been under process of being accommodated to exceptional storms for three years past. For example, an embankment about one hundred feet long across a ravine, and having an escape at one end, seven feet by four feet, was, at the height of the storm, overflowed from end to end. The watershed above this point contains not over ten acres, but for fifteen minutes water flowed on every inch of the surface. Up to the 12th of August, the same sort of weather continued, and since then, though we have had almost daily rains, they have been light and gentle.

The coffee seemed to flourish tolerably through the wind and rain, but on the return of milder weather it became evident that the fungus had seriously extended its devastation, having increased in virulence and spread to vast numbers of plants that had hitherto escaped.

Encouraged by the favourable planting weather, I planted out about 5,000 that had not attained the size that I would otherwise have waited for. The old enemy, the crickets, had not as usual appeared in force about the first of March, and, as they were still apparently absent up to the end of July, I fancied the putting out of even very small plants was tolerably safe. I had, however to suspend operations, as I found vast numbers of the plants cut every morning, but whether it is the cricket or some new pest I am still unable to decide. The cricket usually cuts the stem below the seed leaves, but on the present occasion the remarkable feature of the case is that the depredation is in the majority of cases above that point. This may, however, be owing to the fact that the newly hatched cricket has not the power of jaw necessary to deal with the harder portion of the stem, and consequently it makes its way to more tender spots. Three years' experience taught me to expect the cricket plague early in March and early in September and their entire disappearance about the middle of May and the middle of November, but my theory must be lacking in some essential point, when their first appearance in the year takes place in August. [Their breeding period affected by abnormal weather.—ED.]

I have at length a crop of cocoa on a few of my oldest and best sheltered trees. I showed them to an experienced friend, and he treated them very cavalierly. "You must think about your average," he said, "and not rest much hope on your special trees." All right and true, but when one has been long looking for a fruit forming amid a thousand blossoms, one cannot help asking a visitor to come and see it. My experienced planting friend saw the miserable abortions as well as the pet trees; saw that the former were ten to one of the latter, and issued his decree accordingly. Another friend, not a professional planter, was much refreshed and encouraged by a sight of the same trees and their crops. He has been fighting for two years to establish a field of cocoa, but, so far as I can make out, with no very satisfactory result. He declares his soil and exposure is specially suitable, and, seeing my measure of success. he is determined to persevere till he has 20,000 bearing cocoa trees on his fifty acres. I like pluck! My experience is less encouraging to myself than to my friend. Out of about 30,000 plants first and last, I have some 3,000 alive. One half of these seem to be past the worst, and promising to get on in the future. Of the other half, one part is doubtful, and the remainder not doubtful, but certainly destined to perish. After surviving over twelve months, however, their vitality is wonderful. When about two feet high, the wind strips all their remaining leaves, the stem dies downwards, but within six inches of the ground a sucker takes up the growing, and in many cases succeeds in becoming a tree. My own conclusion is that cocoa will not succeed in soil where gravel predominates, and it will not succeed where the south west wind reaches it, either direct or deflected. My best trees are on a steep face, fronting N E. The south west wind is deflected round the lower ridge of the hill, and strikes the other side of the valley with great force, and the course it takes is distinctly marked by a straight line, dividing the healthy and flourishing cocoa from the seedy and dying. I have carefully experimented on the shade question, and, so far as I have got in its study, with all the varieties at my command, the present conclusion is that none of them require protection from the sun, but all require protection from wind; not only from exceptional storms, but from the steady breeze of every-day weather. Instead therefore of planting shade trees among the cocoa, I would leave narrow belts of jungle, say one chain, at every five chains, both ways, enclosing squares of two and a half acres, the belts running from north to south and from east to west. Then I would reserve half a chain along the line of each belt, in which I would plant, at three feet apart, the quickest growing and most valuable of our indigenous and naturalized timber trees. In three or four years I would clear the jungle belt, and plant the space with cocoa, leaving the wind to deal with the cultivated protection.

If I had recalled at the proper time knowledge I possessed when I was very many years younger, I would, perhaps, have been more successful in dealing with the seed of the Wax-palm entrusted to me, some months ago, but I am always glad to give others the opportunity of profiting by my errors, and I therefore record my experience. The seed of the wax

palm should be put into soil broken up and cleaned to the depth, of from nine to twelve inches, and cover to a depth of two inches. Water as the weather requires, and never indulge in the monkey trick of digging the seed up to see how it is getting on. All seeds grow root before they grow stem, and in their early stages the radicle is far too tender an organ to be exposed above ground with impunity. If left undisturbed, all seeds that retain their vitality will show it above ground during the third, or, at latest, early in the fourth month. This is much about the same time that our indigenous palms take. I believe the seed that came into my hands was, for the greater part, past germinating, but I have enough of plants to establish the tree firmly in the island, even if there were none elsewhere. A few previously germinated seeds that were sent to me are still making no sign above ground.

The dying of many of my Cardamoms after planting out, and the unhappy look of those that survive, I have been ascribing to too much rain, but when I recollect that the habitat of the indigenous species is in the neighbourhood of Padupola, that position becomes untenable, and I am hitherto unable to take up another not equally weak. [On an estate not far from Padupola, the cardamoms grow, but produce very little fruit.—ED.]

To get up Orange plants in this locality appears to be almost a hopeless undertaking. They have two enemies : the caterpillar that eats the tender leaves, and possibly the cricket that cuts off even tolerably hardened branches. I will have to give up trying to grow them from seed, and try what can be done with cuttings.

CEARA RUBBER —It is just ten months since I put down the first Ceara rubber seeds, and I have already collected and sown ripe seeds, produced from the resulting plants. The largest tree is about fifteen feet high, branches at about seven feet, and now shades a circle of ten feet diameter. Some others have reached the height of ten feet without branching, but the greater number have branched at from two and a half to five feet, and the seed-bearers are those that have branched lowest. As to the growth of this product there is no longer a question, and the value placed on the only sample sent from Ceylon seems satisfactory; but we have much to learn before we can pronounce it a paying industry. At ten feet apart, we will have 434 trees to the acre, but we are still in utter darkness in respect to yield per tree and the cost of collection. Till those two questions are settled, it can hardly be considered safe to go largely into it. As for the cost of cultivation, exclusive of collection and preparing for the market, it would after the first year be trifling, as it is evident that the tree is able with twelve months' start to hold its ground against all competitors. The field of conjecture is a wide one, and I dare not go a step further in it. In front all looks an open plain, but beware of sloughs and pitfalls.*

In re Eucalyptus globulus, Tropical Agriculturist vol. 1, p. 415., will hardly account for the infection of other species of plants, but proves this particular tree subject to some mysterious disease. [Which disease is said to attack cinchonas entirely beyond the influence of eucalypti.—ED.]

TEA IN UPPER INDIA.

(From the *Indigo Planters' Gazette.*)

The land of the Doon has a beautiful slope, just sufficient to admit of proper drainage. The town of Dehra which stands on the watershed almost exactly half-way between the Ganges and the Jumna, is 2,345 feet above sea level. The Ganges, 30 miles to the east, has a height of 1,050 feet, and the Jumna, an equal distance to the west 1,000 feet. This is an average fall of 34 feet per mile, ample for drainage purposes, and not by any means too much, as when the slope is great, the soil, and particularly the humus, which forms the most valuable part of it, gets washed away. The geological formation of the Doon gives evidence of its having been the bed of a mighty river at some time, the traces of the current on the banks being most distinctly marked on the Sewalic range at Hurdwar, at which point the river evidently found its way to the plains, as the Ganges does now. From the present formation, however, it is clear that the existing soil, with its exuberant humus, is the product of washings from the Sewalic on the south, and the Himalayas on the north. Countless streams are still bringing in fresh supplies from the everlasting hills, and thus the luxurious richness of the soil is fully accounted for. Prospecting for good land, we have personally had the soil examined to the depth of 12 feet, and in nine trials out of ten, have found no break in the continuity of the soil, and it were strange if such a soil should not prove good for tea. Here and there one comes across beds of gravel, over which tea grows well for a few years, till the tap-root reaches the stratum of gravel, when all growth and production of leaf practically cease ; the tap root cannot reach the source of nourishment, and during the dry weather, such a thin soil as we are speaking of, gets denuded of its moisture. The soil is particularly rich in plant-food, and is easily hoed, unless during the early spring months, when it becomes hard from constant baking by the sun. The Doon is furnished with canals, bringing water from the many streams of the Himalaya mountains, but unless for seedlings, this water is of no value to the tea planter. The geological feature of the hills above Dehra is lime, and the water is so impregnated with this lime, as to be almost fatal to tea. A field watered plentifully from the canal, will, as a rule, give scarcely any leaf for a year or two, and in many gardens the track of old village canals can still be traced, the line being absolutely bare of plants. Much has been written on the value of lime to the soil, but in too many cases the fact has been entirely overlooked, that lime does not enter largely into the composition of the tea plant. In fact, the proportion of lime in the ashes of the plant is only 4½ per cent while in coffee it is 60 per cent. Lime is, therefore, one of the best ingredients for coffee soil, and in this way it has come to be considered good for tea as well. This is a great mistake, and hence irrigation in the Doon is a doubtful blessing so far as tea is concerned. The Doon planters are so alive to this fact, that in letting spare land to rayats, it is customary to stipulate that no rice shall be grown on the land. Rice requires so much water that a year or two of its cultivation destroys the land for tea, unless several years' fallow intervence. [We have now discovered in Ceylon that clayey and ferruginous soils in which lime is not present in sufficient abundance for coffee culture, answers admirably for tea.—ED.]

The labour difficulty never arose in that happy valley. The country around is very scantily inhabited, so much so indeed, that local labour is almost unknown. One result of this is a scarcity of food grains, large supplies of which come from Saharunpur and Meerut. This forms one of the traffic items on which the promoters of the Doon railway rely for their dividend. We have no doubt that another result of the railway will be to bring a larger population to the Doon, the more so when the Oudh and Rohilkhund line is extended from Moradabad to Saharunpur, with the branch to Roorkee and Hurdwar. The tea planters of the Doon rely for their labour on im-

* The rapid growth of this plant surely indicates its use for shelter belts. It could be planted thickly and thinned out as experience dictated.—ED.

migrants from the densely populated districts of Sultanpore, and other of the more crowded parts of Oudh. These people must lead a hard life of it in their homes, when they leave their native villages and travel so far for such small wages. The men usually leave their wives and families behind, until after a couple of years they can save twenty to fifty rupees, when they frequently take leave and go to their homes, bringing their household gods—their *lares* and *penates*—with them on their return. Thus the Doon villages are quietly being peopled by these useful *Poorbeahs*, who as a rule, have no very high caste, and become steady cultivators of their own little leased farms. In arranging for labour, it is not necessary to make any contract, the coolies being engaged as monthly servants, and provided with free houses. There the contract ends, as, of course, the labourers get free medical attendance and medicine, and where ground is available, are also allowed to cultivate small patches of vegetables. In the better conducted gardens, they are encouraged to do this, as a plentiful supply of fresh vegetable diet, tends to keep them healthy. The prices of labor are as follows :—

	R. per month.
Field hands—— —— ——	4 8
Factory hands —— ——	5 0
Women —— —— ——	3 0
Boys and girls 1-8th to ——	2 8

Women are employed at light work when there is no plucking, such as carrying manure, weeding nurseries, classing teas, &c. During the leaf season, women, boys, and girls usually make more than the men, as all leaf plucking is piece-work, the customary rate being three pies per pound, which is R1·4 per maund. These *Poorbeahs* are very fair workers, and as a rule give little trouble, if treated at all fairly well. This labour question is one which gives the North-West planter an immense advantage over his brethren who obtain their labour under the cover of legal enactment; for about seven rupees per month, he can have labour to the extent of one man and-a-half per acre, which would cost an Assam planter from R12 to 15 per month. Thus it is that up-country planters having gardens yielding generously, can turn out their teas for four annas per lb, a price which more than compensates them for the heavy carriage between their gardens and Calcutta.

[Ceylon cannot possibly complete with the Dhoon in regard to cost of labour, and yet, if the Dera estates are now yielding profits, there has been a change for the better within the past few years.—ED.]

The course of cultivation is very regular, the rainy season being punctual, and from one year's end to another the routine of one month, is exactly the same for every year. Towards the end of November, or early in December, when the season's crop is all classified and packed, pruning begins and while this is going on, manure is brought from the various pits where it has been stored, and is piled along the walks of the garden. The best men are set to the pruning, while the ordinary field hands commence the annual deep hoeing, trenching it is called, but erroneously so, it being only an extra deep hoeing, and this is perhaps the only job which breaks the planter's temper. He knows perfectly well that much of his next season's crop depends on this hoeing being done thoroughly, and to ensure its efficiency, he usually gives a small *nirik*.—[Task. ED. C. O.] However, unless close personal supervision be given, he will be disappointed. The order we will say, is for a 15-inch hoeing, as a rule he will be content with twelve, but calls it fifteen to keep the men up to the work. A 12-inch perpendicular hoeing would work wonders with next year's leaf, but the coolie will persistently give him a 12-inch slope, and by sloping even by more than ordinary, will sometimes present for measurement and examination a 15-inch slope, but by the well-known rule of the hypothenuse, the planter knows that a 12-inch slope at an angle of 45°, means only a perpendicular depth of eight inches and-a-half. This is not the place to moralise on the immense importance of a good deep hoeing, we shall, however, return to the subject on some future occasion. About the middle of January the pruning ought to be done, when a number of the bigger lads are set to work opening out the roots, preparing for the manure, this the women and boys carry from the walks, in small baskets, each containing the supply for one plant, say about ten seers. It is astonishing how quickly a large number of coolies get over such work in the cool [often very *cold*.—ED. C. O.] weather of January or February. A second batch of men with hoes go behind the basket women, and cover up the manure around the roots. This work goes on till the end of February, when the whole month of March remains to prepare for the coming season. This month is usually occupied in putting the walks in order, in attending to repairs in the factory and coolie lines, and in getting into working order the factory plant. As we have said, the leaf is ready with astonishing punctuality, one or two days on either side of 1st April.

THE COOLIE OR CHEAP LABOUR QUESTION.

is the subject of considerable agitation in Queensland at present, and it may be doubted whether the opposition which is being offered to the introduction of Indian coolies as of Chinese would not be extended to our Sinhalese so soon as they made their appearance. Brisbane, the capital, is the headquarters of the opposition. There the working classes naturally object to the competition of cheap labour; but they do not sufficiently realize the impossibility of cultivating sugar or other tropical produce in the northern division of the colony by the agency of European labourers even if such were available. The Ministry appears to be in a quandary, and have just laid before Parliament correspondence with the Indian authorities which closed on the 21st June last. Under the arrangements made with a representative of the Queensland Government and Mr. Buck, Officiating Secretary to the Government of India, an employer would have to pay £18 for each emigrant, and give a bond of £12 for his return passage. "It is understood," says Mr. Buck, "that the chief protector of immigrants at Brisbane, in whom the control of Indian immigrants is vested by the draft regulations, is a permanent Government official, charged with the general superintendence of all immigration affairs," and Mr. Buck further points out the necessity of that officer having had Indian experience, and a knowledge of the Indian language. The Queensland premier, Mr. McIlwraith, closed the correspondence in a letter from which the following is an extract :—

"Under the regulations, as approved by the Governor-general, there is nothing to prevent time-expired immigrants from engaging themselves as domestic servants, &c., to town residents and others entirely unconnected with tropical agricultural pursuits, the effect of which would be that these immigrants would not only come into active competition with European labourers, but they would escape that supervision at the hands of the Government protectors which not only the Indian Government but the Government of

this colony are anxious to secure. These alterations, I have no doubt, will be acceptable, as I observe, in looking through the correspondence on the subject of coolie emigration, that it is the desire of your Government that coolie immigrants should, if possible, be confined to field labour.

"You will note that a slight addition has also been made to the form of contract, whereby the immigrant binds himself, before leaving India, not to work for any employer in the colony other than one engaged in tropical or semi-tropical agriculture.

"With regard to the appointment of a special officer with Indian experience and a knowledge of the Indian languages, as Chief Protector in Queensland, I have to inform you that the Government will have no objection to the appointment, provided his salary be not made a charge upon the public funds of this colony. There is, however, no necessity for the appointment of such an officer by the Indian Government, as our Immigration agent, who is also chief inspector of Pacific Islanders, has a well-organized staff, consisting of officers residing in the several districts of the colony charged with the duty of carrying out the provisions of the Pacific Island Labourers Act, whose work would be available for the performance of the usually undertaken by the Chief Protector."

Since then—or on July 26th—a meeting, largely attended, of the citizens of Brisbane, has been held with the Mayor presiding, at which the following resolutions were carried :—

That this meeting views with alarm the proposal to introduce coolie labour into Queensland, being firmly convinced that such a course must entail the most serious consequences to the European working class of the colony.

That this meeting emphatically protests against the industrial classes of Queensland being brought into competition with semi-civilized and underpaid coloured labour, and is determined to maintain this colony as a home for the European races.

That this meeting urges the establishment of branches of the Anti-Coolie League in every town in the colony, so as to unite the people for the purpose of averting the threatened danger.

That a petition to the Legislative Assembly be prepared in support of the bill for the repeal of the Coolie Act, and signed by the chairman of this meeting on its behalf, and that the senior member for the city be requested to present the same.

After this, Mr. Griffith, the leader of the Opposition in Parliament, tried to steal a march on the Ministry, by moving for the repeal of a Cooly Act passed some years before. The matter is thus referred to editorially by the *Queenslander* :—

Without going so far as to say that Parliament cannot restrict the importation of coolies unless by virtue of an agreement with the Indian Government for their introduction, we agree—nor do we think that Mr. Griffith will deny—that legislation of some kind is imperative. There is nothing to prevent employers at present from introducing coolies in the manner suggested by Mr. Macrossan, and the agreements made with them in Ceylon would unquestionably be validated by the Masters and Servants Act in this colony. There can be no question that if we desire to restrict coolie immigration, or even to entirely forbid it in the form of hired labourers, we can do so by legislation in the colony, apart altogether from the regulations of the Indian Government. On the whole the better course will probably be to amend the present Act in the manner proposed by the Government—that is, as a tentative measure to enact that any regulations that may be adopted shall require validation by resolutions passed by both House of Parliament. This bill may be passed by common consent in an hour, and will provide for present exigencies. If when the regulations come before Parliament they are deemed impolitic they can be rejected, and such further legislation be carried out as the circumstances of the case appear to require.

Altogether it seems to us that there will be no peace in Queensland over this Labour Question, until the colony is divided into two : the northern and tropical portion being founded as a Crown Dependency, in which the fact will be recognized that Europeans must supply the capital and do the supervising, but not the field-work. For the latter "native" labourers —whether Kanakas, Indian coolies, Chinese or Sinhalese—must be employed or farewell to the success of sugar, coffee, cocoa and other plantations in the promising settlements of Northern Queensland.

PLANTING IN THE EASTERN ARCHIPELAGO.

The *Java Bode* of the 31st July contains a report laid at Amsterdam before the shareholders of the Company formed to turn the island of Batchian to commercial account, in which it is stated that the Company's operations will be chiefly directed to trading, until sufficient coolies have been engaged from Java and elsewhere to promote extensive cultivation, which is intended to be the principal business conducted. Coffee and nutmeg planting will be first taken in hand. Cocoa growing will only be undertaken when that plant shall be found not liable to a disease which attacks it in many places. In the meantime, the preliminary operations will also comprise the collection of dammar and other jungle produce. Turning the sago forests to account awaits better means of transport. During the short time the Company has had an establishment at Batchian, that island was visited by a British coaster, besides other vessels.

PLANTERS AND THEIR AGENTS.

(From the *Madras Mail*, Sept. 12th.)

"Dry Cherry" writes :—"The natural excitemene attending the prosecution of the gold industry in the Wynaad is, I fear, hurtfully drawing away from the study of their own interest the attention of those entirely dependent for their future on the success of coffee and cinchona cultivation. I am myself nought but a baby-planter of a few years' experience, but that experience has been long enough and close enough to convince me that it is not the seasons which have been or are the planters' sole enemy, but those gentlemen yclept agents, who certainly look after No. 1. As a text for further observation, I will detail my past season's experience. I sent down to my agents 4,800 bushels of cleaned coffee, almost entirely consisting of parchment. The out-turn on the average was 106 bushels to the ton, that in the case of dry cherry reaching in one instance to the unprecedented number of 187 bushels. Let my readers connote the foregoing with the following facts : (1). I had taken every precaution to thoroughly dry my coffee,—the best samples I weighed here strangely enough are bulk for bulk a trifle lighter than the coffee after it was cleaned and put on board ship ; (2). I took one lot which had been all picked from the same field, pulped at the same time, and dried for the same period ; I divided this into three consignments, and sent it to the agents under three marks, and the out-turns varied from 98·5 to 122 bushels to the ton ; (3). The large quantity I sent down was delivered to the agent exactly to the number of bushels I had measured it here on the estate. Putting these facts together, it will not require much mental exertion, either deductive or inductive, to conclude that my 4,800 bushels never entered the agent's yard in their fulness, and that the receipt I hold to say they did, is but one of those happy literary figments that

grace the course of an agent's dealings with his constituent. I would fearlessly commit myself to a moderate bet, that not even a single load of coffee, after having been shaken over sixty miles of rough road, in a springless cart, would turn out in quantity at its terminus exactly what it was at the start. How manifold would my confidence be increased if I came to bet on 4,800 bushels, instead of sixty! The solution of exactitude is very transparent. My despatch note was no doubt received as really representing the quantity delivered. Upon the basis of such accepted delivery, all the agent's returns of out-turns, &c, were thenceforward based, but it must be apparent that inferentially these returns are false in fact as they are unintentionally dishonest in creation and carelessness. I have mentioned that I took particular care in drying my coffee, and that the best samples in my possession are bulk for bulk lighter than the mass they represent, as that left the agent's hands. My fellow victims may then fairly conceive the tonic gurgulations that I became the subject of, when looking over the outturn statements; I found 4½ per cent. had been deducted as 'driage' from the quantity I sent down. Surely this word is a misnomer. Influenced, no doubt, by the climatic operation here, I find that the coffee when it gets to England, undergoes still further 'driage' to the extent of 1½ per cent. Thus in all the reduction in weight amounts to 6 per cent., and I would ask any planter who has studied the matter, if such diminution could possibly have occurred under ordinary treatment.

My coffee on the average was sold for R750 the ton; against this I have to put the following charges:—

		R.
1.	Discount—for what purpose charged heaven only knows, 1 per cent	7·50
2.	Guar'd, commission—an upward appeal can alone explain this, ½ per cent ...	3·75
3.	Freight, brokerage, etc., 13 per cent ...	97·50
4.	Driage 6 per cent	45·00
5.	Cleaning charges	50·00
6.	Transport	75·00
7.	Interest to Agent	67·50
		R346·25

Taking the average Wynaad yield at 3 cwts. to the acre, to produce one ton I have to maintain 6⅔ acres. Deducting 346·25 from 750, I have thus R403·75 left to do this, or say, R60 per acre. In my opinion, an estate to be properly maintained ought to have spent on it per annum R80 an acre at least, so that receiving R60 for what costs me R80 to produce, I, as a planter, contribute generally to the public benefit, and particularly handsomely to the income of my agents. What a cheering prospect before me! I come now to the main object of my letter. My case I know is not singular, and that my position is better than most of my neighbours! I ask myself, and I want my brother planters to ask themselves, why we should go on submitting to the present state of things? Let us have a 'Planters' Union.' The agents have established a union amongst themselves; they charter vessels to carry our coffee, share the profit of the transaction between themselves, and dictate the rate of freight to us; they act similarly as to the curing, shipping, interest, and home charges. In all parts of the world, the binding of a common interest by the tie of a healthy co-operation has been most beneficial in its results; why cannot we planters learn a lesson from others? I may be answered that the agents have us in their clutches; that we are all, generally speaking in their debt, and cannot escape from them: but what often is impracticable and impossible to individual intention may be accomplished by united action. Let us combine and start a company, such as the Neilgherry Lands Investment Company, content with a moderate rate of interest; let us incorporate ourselves legally as a body, and we can then borrow money from the banks at a far less rate of interest than the agents charge us; let us start an Insurance Fund, wherefrom the planter who has fairly worked his estate and under the control of the Committee of the Union may be strengthened in a bad season for efforts in the future; let us start an Agency in England, and protect ourselves from the cost of paying for the maintenance of a credit there, which our necessities here create for our so-called agents. Let us do some or all of these things, and the coffee industry may yet look up and hold its own. Let us forbear and inscribe Ichabod on our gate-posts. To shew that I am serious, I am quite willing to put R20,000 down to promote such an undertaking as I propose. For lack of leisure I enunciate my views in a very crude form, but will be most happy to interchange ideas with any or all of my fellow-planters. If any notice is taken of my suggestion, I would propose that our old friend J. B. Buruett be hunted out of an obscurity which his wide experience does not entitle him to occupy, and entrusted with the digestion of my scheme."

LEDGERS (CINCHONA) IN LINDULA.—Mr. Parsons sends the following encouraging report:—"Perhaps you will be interested to learn that Mr. Cameron's 18 months' old Legeriana trees on S. Regulus show an analysis of 2·93 per cent crystallized sulphate of Quinine. The sample was taken from ten trees, and the result must, I think, be considered somewhat encouraging."

THE NAGA HILLS.—Mr. McCabe's administration report of the Naga Hills for 1881-82, although considered "rather sketchy and vague" by the Chief Commissioner of Assam, affords "an extremely interesting" summary of the events of the year, which Mr. Elliott has digested with "great satisfaction." Mr. McCabe suggests in his report that the great Nambar forests be partially reserved, and a portion thrown open for tea cultivation. In this the Chief Commissioner has concurred, so that the planters are now to be invited to take lots of land for cultivating.—*Statesman.*

TEA IN AUSTRALIA AND AMERICA.—We have already ventured to predict that, at least three million pounds of tea will this year be necessary to meet the requirements of the Australian market. Various other estimates have been made, ranging from two to two and-a-half million pounds, but we still adhere to our own estimate of three as a minimum. The latest news from Australia tends to confirm the correctness of this forecast, and a considerable quantity at a recent Calcutta sale, was purchased for that market. Mr. Sibthorp has recently brought an encouraging report from America. There the preference for the finer scented quality of China, and more particularly of Japan, has obtained such a hold on the public taste, that he does not expect much will be done in those classes. There is, however, an immense field for tea to sell at about one shilling and sixpence. This is very encouraging, and by and by the better classes will come to learn, that Indian Pekoes will bear comparison with certain classes of very expensive China teas, and thus a footing will soon be attained in that great country, with its teeming and ever-increasing population. Mr. Sibthorp sold a quarter of a million pounds, during his short stay in America. Taking these two markets together, we should not be surprized if five million pounds were this year retained for transmission to them. This will be a very sensible relief to the London market, and this should always be kept in view, as it, more than anything else, affects prices.—*Indigo Planters' Gazette.*

INDIAN TEA COMPANIES.

The working of thirteen Companies has been analyzed and tabulated by the Planters' Stores and Ageney Company, Limited, and is published in the *Indian Agriculturist*. Of course dividends depend not so much on the result of particular years, but on the capital expended from first to last, and others besides the Assam Company may have got their property for a mere song, at the expense of previous shareholders. This premised, we may say that the highest yield of tea is shewn by the Borelli Company, whose yield per aere over old and young cultivation was 470 lb. in 1880 and 524 in 1881. The eost per lb., including all eharges, was 1s 2½d in 1879; 1s 2d in 1880; and 11½d in 1881. The gross prices (including sales of tea seed, etc.) were 1s 7¾d, 1s 4d, and 1s 4⅜d. Profit per lb. 5½d, 2d, and 5¼d. The dividends varied 10 per cent, 4, and 10. The Assam Company, on the other hand, which divided 35 per eent in 1877, fell to 10 percent in 1879, taking 2 per cent of this out of the reserve fund; the rate being 7 per cent in 1880 and 10 in 1881. The yield per acre of tea was 400lb. in 1880 and the same in 1881. The tea cost for the 3 years 1879–81, 1s 5⅝d, 1s 2 7/16d, and 11¾d. The profit per lb. was 1⅜d, 1 5/16d, and 4⅝d. It is possible that extensions may have been charged against revenue instead of capital? Looking at the figures for prices in the past three years the course has generally been downwards with them, while, in consequenee of lower cost of production, the result, no doubt of enforced economy, profits were higher. For instanee, as the figures we have quoted shew, the Borelli Company had 5½d profit in 1879 out of 1s 7¾d per lb., while in 1881 1s 4⅜d gave 5¼d profit. The ease of the Darjeeling Company was exceptional, shewing rising priees and increasing profits, thus:—

	1879.	1880.	1881.
Price per lb. ...	1/6½	1/6⅝	1/7½
Profit ,, ...	3⅛	5	6

The lesson taught is that of the most rigid economy, for the following note, referring to four leading companies, shews how prices have tended downwards generally since 1876:—

Average gross price proceeds sale of crops including all receipts by gain in exchange and sale of tea seed:—

	1876.	1877.	1878.	1879.	1880.	1881.
	s. d. per lb.	s. d. per lb.	s. d. per lb.	s. d. per lb.	s. d. per lb.	s. d. per lb.
Assam Co. ...2	4½	1 10½	2 0½	1 7⅜	1 3½	1 6¼
Borelli Tea Company ...2	0	1 11¾	1 11½	1 7¼	1 4	1 6⅛
Doom Dooma Tea Company 1	10½	1 3¼	1 7¾	1 5¼	1 2⅛	1 2¼
Wilton Tea Company ...2	1½	1 8½	1 9	1 5	1 1⅝	1 4¾

While 524 lb. per acre was the highest bearing rate, it was so low as 192 in the ease of the British India Company. This Company made no profit in 1879 and 1881 and incurred a loss in 1880 of 0¼d per lb. Exeluding this ease, the average of 10 companies was 365 lb. per acre.

The following, whieh we take from the *Indigo Planters' Gazette*, shows that the average eost of produeing tea on some of the largest eoncerns in India in 1881 slightly exceeded one shilling per lb. What is the average in Ceylon? Of course it will be lowered as experience is gained, larger quantities made and as maehinery is introduced:—

The following is a list of cost prices of 1881:—

Assam Co. ...	11·5d	Lebong ...	12·5d
Borelli ...	11·5d	Jorehat ...	13·125d
Doom Dooma	12·125d	Darjeeling ...	12·72d
Scottish Assam ...	12·25	Land M. Bank	13·125d
Jhnnzie ...	11·125d	Dejoo ...	12·25d

The average of these is 12·225d.

QUEENSLAND AND COOLIES: THE PROSPECTS OF TROPICAL AND SEMI-TROPICAL AGRICULTURE IN AUSTRALIA.

The fact that not only European directors of labour are seeking new homes in the great Island Continent of the south, but that, for the first time in their history, the Sinhalese are seeking

"fresh woods* and pastures new"

for their labour, more than justifies us in furnishing our readers with sueh further information as is within our reach. When in Australia, we frequently discussed with friends there the relations between south and north, involving questions almost as burning as those which finally led to eivil war between the northern and southern States of what only now can really claim the title of the American *Union*! Although, happily, the iniquity of slavery does not exist and is never likely to exist in Australia as a eurse and a complieation, from which only a terrible internecine conflict freed the Americans, yet the parallel as regards the two countries is curiously elose in the matter of aboriginal races which are melting out of existence in the presenee of the energetie land-tilling and manufacturing, navigating and trading Europeans who have taken possession of their hunting-grounds. There is, of course, no comparison of physical vigour and lively intelleet between the red Indians of America (about whom, however, too much of the halo of romanee has been thrown) and the miserable blacks of Australia, but the fate of both is alike, in that they are doomed to perish. The lands whieh once knew them shall speedily know them no more. Neither for themselves nor for the superior races will they work, exeept in very rare eases and within narrow limits of employment, and as their hunting-grounds are fast being converted into sheep and eattle runs, farms and orehards, cities and manufactories, and their fishing pools and rivers utilized for watering flocks and herds, sluieing of mines and irrigating farms, they must give up the earth to those who can properly develop its resources; who have eome up to possess the land and to inerease and multiply on its surface. The disappearance of the aborigines in the temperate portions of Australia, where the white man can work and enjoy life, would be merely a matter of sentimental regret to the few, while to the many—the working classes—the removal of an inferior race, individuals of which did occasionally compete with them in the management of horses and as police troopers,—would be hailed with rather a sense of relief, we fear. But the ends of the world are eoming together, and as one ethnic problem is solved by the disappearance of a raee to whom eivilization was fatal, another *swarms* on the seene (that is the true mode of expressing the phenomenon) in the shape of the ubiquitous and irrepressible Mongolian, who flourishes on the erumbs of eivilization and often by eombined industry, sagaeity and enterprize takes his plaee amidst the amenities and the luxuries of the higher ranks of life. Witness the wealthy and hospitable Mr. Kong Meng of Melbourne, the late Hon. Mr. Whampoa of Singapore, and others. As "fossickers" of dirt heaps from whieh Europeans have extraeted all the visible gold, and even as market gardeners (utilizing manure and water and growing eabbages, cauliflowers, peas, potatoes, and other vegetables, but for whieh many a white man's board in arid Australia would be but scantily supplied with anti-scorbutie food),

* The true reading.—ED.

the labouring white man might tolerate the Chinese. But, as has been shewn over and over again, the bounds of toleration are passed, when the pigtailed men bring down the rate of wages on the shipping wharves, in the coal mines, in the cabinetmaker's shop and in other important departments of labour and handicraft. Of course, to an onlooker, not personally interested, as was the case with us, the abstract and equitable question of free trade in labour as in commodities was obvious and simple, and we felt ourselves on strong ground in arguing that the yellow-skins had as much right to come to labour and trade in Australia as the white skins had to enter China for similar purposes. The answer of the working classes, as interpreted by their spokesmen on the platform and in parliament was:— "We mean to keep this glorious heritage of ours free from the contaminating influences of an inferior and a foully immoral race: that is our firm determination," the real meaning of which amongst the labourers and artizans was, "We are determined that our scale of wages and our standard of living shall not be lowered by competitors who are ready to work for half or quarter our normal rates of 6s to 10s per day of eight hours." As universal suffrage prevails in Australia, the working classes control legislation, and there are but few constituencies in the south (except in Western Australia which has only recently ceased to be a depôt for convicts) which would return to parliament and give the chances of public life to any man who adhered to the abstract doctrine of the equal rights of all men to go anywhere to live and labour, so that they do not violate law or disturb order. We shall not soon forget the embarrassment of a member of the New South Wales Parliament with whom we crossed the Blue Mountains by the celebrated zigzag railway and discussed the whole question. He conceded all the principles of abstract right for which we contended, but he ever fell back on the popular argument of self-preservation. The white races had possession of Australia, and for themselves and their children they must preserve the inheritance. They had rights founded on the principle

> That he should take who has the power,
> And he should keep who can.

Above all, the dignity and the rewards of labour must not be lowered. In this spirit, even so zealous an advocate of free trade as Sir Henry Parkes has been as ready to to further anti-Chinese legislation as the arch-Protectionist, Graham Berry of Victoria. And the strange part of the matter is, that, notwithstanding our treaties with China, the Imperial Government has repeatedly advised the Queen to consent to such legislation.

But although we could largely sympathize with the feelings, considering the position of those who cherished them, which dictated anti Chinese and anti-cooly legislation affecting the temperate portions of Australia, we did expect that the leaders of thought in the southern colonies would recognize the necessity of exceptional treatment of the tropical portions of their vast territories: the northern portion of so-called South Australia and Northern Queensland for, in Australia, be it remembered, the further north; we go the hotter does the climate become, because the nearer do we get to the equator. We always contended that both should be separated by a convenient geographical line and ruled by Lieut.-Governors, Superintendents or whatever designation might be preferred, on the principles, generally, which are applied to Crown colonies, like Ceylon. A system, indeed, approaching this principle has been applied by the Government of so-called Southern Australia to their Northern Territory by the appointment of a Resident at Port Darwin. In company with Mr. Buck, the Commissioner for India, now at the head of the Indian Agricultural Department) and the gentleman who succeeded him at Melbourne, Mr. Jas. Inglis, we discussed the whole question in Melbourne with the former able editor of the *Queenslander*, Mr Gresley Lukin. Mr. Buck, who took great interest in the subject and who has elaborated a scheme of cooly immigration to Queensland, as also Mr. Inglis, who was enthusiastic on the subject of a closer union between Australia and India, fully supported our contention that by means of cooly labour alone could the resources of tropical Australia be developed, seeing that the supplies from the Solomon group and other isles of the Pacific were becoming so scarce that even Fiji was in danger of coming to a standstill for want of labour. The chiefs objected to the departure of their fighting men, and the Kanakas, who had returned with guns amongst other trophies, were often only too ready to use their acquisitions in thinning a population already diminished and diminishing from other causes besides violence. To our surprize Mr. Lukin objected to black or coloured labour even in the tropics: white men, he insisted, could do all the work! When we mentioned this to a sugar planter on the Burdekin, he exclaimed: "*Mr. Lukin is only a newspaper editor*, and knows nothing about it!" which, we said, was rather rough on men who were only newspaper editors. It was in vain we pointed out to Mr. Lukin that the coolies would only come to sojourn—to engage for fixed terms in tropical labour and to return, and that we contemplated a form of local government under which the question of the franchise could not be raised—a benevolent despotism, tempered by an open council and public opinion, such as we have in Ceylon. Mr. Lukin, who had had the advantage of residing in Queensland, insisted that white men could labour there from the tropic of Capricorn at Rockhampton to the extreme north at Cape York and Thursday Island. Subsequently we had the opportunity of judging for ourselves, not only by visits to the splendid sugar estates which line both sides of the Pioneer river in the Mackay district, but amidst the mangrove swamps of the Burdekin delta, where quinine and chlorodyne were indispensables. Most part, even of the tropical portion of Queensland, is fairly salubrious, but, except on the hills, the climate is at times hotter far than even in Kurunegala and Matale, and there are many fever-haunted localities which have claimed and will claim their victims. Even in the cleared and cultivated portion of the Mackay district, a touch of fever occasionally reminds dwellers on the banks of the Pioneer, that a rich soil and forcing climate, if they have their advantages, have also some drawbacks. The proportion of white labour to black which we saw on the Mackay sugar estates, and which, no doubt, the experience of about a dozen years had settled as the best, was 20 per cent of white labour to 80 per cent of black. The white labourers ploughed the land, drove the waggons and looked after the horses, exceptional aborigines or Kanakas who could perform such work being very rare. In the moderate climate of Mackay the white men followed their ploughs: in the more northern delta of the Burdekin, with its higher temperature, the ploughs employed were the American "sulkies" on which the ploughman sat and drove. The Kanakas perform the field-work and are also (women included) employed in feeding cane to the sugar-mills and other work connected with the manufacture of sugar, molasses and rum. When we saw the Pacific islanders vigorously cutlassing down the cane beneath a vertical sun and in heat which was stifling, as no breeze could pass through the dense grove of tall stalks, we felt that if white men could be got to perform such work, "sunstroke" would speedily claim many victims. We could not help, however, remembering Messrs. Hornby & Sons' most effective hedge-trimming machine, which we had

seen at Kyneton, cutting the top and both sides of a furze fence, while pulled by a horse only on one side of such fence. All was done by the adjustment of the guillotine apparatus. What we said on that occasion occurred to us again and again, and we deem it not impossible that a modification of the hedge cutting machine may largely supersede human labour in the mere cutting of sugarcane, and even in trimming off the tops which the Kankas did on the field with their cutlasses. Indeed we believe Messrs. Hornby & Sons' machine has already been used to shave off at the surface the grass tussocks which in large portions of New Zealand render the clearing of land for agriculture so difficult and expensive. The era of cheap as well as effective machinery to supersede human labour in tropical field work has not, however, yet arrived, and clear it is that if, now that the Pacific field of labour supply is about exhausted, while cultivation is largely extending, the sugar planters of Queensland are not able to procure a supply of cheap cooly labour, they must retire from competition with Mauritius, Guiana, Java and Cuba as sugar growers.

We have mentioned "separation," a political cry well known in Australia. The latest community to raise it is that of Townsville, the Australian Naples, "beautiful for situation" and destined to be the capital of Northern Queensland. It will, in the future, profit largely by the sugar and other tropical culture in the deltas and alluvials of such rivers as the Burdekin and the Herbert with the hill and mountain ranges in which those streams have their origin. But as yet its prosperity has been mainly furthered by the pastoral interests of which Mr. Towns, after whom the city is named, was one of the pioneers and the mining enterprize of which Charters Towers, to which the railway is rapidly approaching, is the centre. The cry of "separation," raised by the Townsvillites, has, therefore, no reference to a desire to obtain coolies as labourers: quite the contrary. North unites with south (except the small but influential body interested in sugar cultivation, including, we believe the present premier of Queensland), in denouncing the introduction of black labour to compete with white, after a fashion which raises grave doubts in our mind if the Legislature of Queensland will sanction the scheme which the MacIlwraith Ministry have settled with the Indian Government for the introduction of coolies; and we only trust our Sinhalese friends will not find that their "lines" have fallen to them in the reverse of pleasant places, if public opinion develops as it is doing. Capitalists, large and small, who contemplate sugar planting and other tropical culture, will welcome them, and especially those who have "scrub" (that is tall, dense forest) to fell: but cursing instead of blessing will be meted out to them by the white labouring classes and their friends. The main reason, it is alleged, why, headed by Alderman Simpson, the residents of Townsville have raised the cry of separation, is that the construction of a jetty or breakwater, which Townsville urgently needs to facilitate her commerce, has been temporarily stopped. At present an ordinance is in existence permitting the introduction of Indian coolies, but it remains to be seen if even Mr. MacIlwraith's Ministry can induce the Legislature to sanction the rules under which this law is to become operative. Until such sanction is given and the consent of the Indian Government is obtained, no coolies from India can be introduced. But we suppose the present laws suffice for Sinhalese as well as for Kanekas. The wages are exclusive of rations, and while meat is plentiful and cheap we fear there may be some difficulty about rice, on which an import duty of we believe one penny per lb. is levied. Now Queensland is suited for rice culture, and we feel confident will become a great rice-growing country. The Sinhalese immigrants would be the very men, if they could be spared from the work of the sugar plantations, to establish this industry. Initiate it they cannot, for trials have already been made and with perfect success. Our old Scotch friend Mr. Alexander Macpherson shewed us some fine specimens in the Queensland Court at Melbourne grown by himself. But even Macpherson and other growers of rice* were anticipated by nature, for the rice plant is indigenous in the swamps on the borders of the Gulf of Carpentaria (whither a transcontinental railway, with its terminus at Point Parker, a sheltered port, whence steamers can make direct for India, is likely soon to be extended). So plentiful and so prolific is the rice plant in these swamps, that at certain seasons the pigeons from New Guinea (less than eighty miles distant) are described as flocking in *millions* (that is the word used in an official report) to feed on the grain. What a paradise of rice as well as pigeons would the Sinhalese deem the river-fed swamps on the borders of the Gulf of Carpentaria! To convert those swamp into cultivated rice-fields, as well as to profitably grow sugar, coffee and other tropical produce, the one great want is labour. White labour, aided by science, can do much, but we strongly suspect that to the people of India and Ceylon remains the task of subduing and rendering fruitful the alluvials and swamps, the hills and the mountains of Northern Queensland and tropical Australia generally: always, of course, under European guidance and command. Coffee, like rice has been tried in Queensland, and there can be no doubt of its success, as far as soil and climate are concerned. Bonwick, in his valuable compendium, "Resources of Queensland," states that "coffee plantations flourish at Tingalpa, Redbank, Eightmile Plains, Mackay and the Lower Herbert;" but to dignify the small patches of coffee which exist at the places named with the title of plantations, reminds us of what James Boswell's father said of Dr. Johnson:—"He keepit a schule an ca'ed it an Academy." The goodness of the soil in those parts where disintegrated volcanic rock and coral are saturated with decayed vegetable matter, will compensate for occasional prolonged droughts. But rich soil is as favourable to weeds as to coffee, and for weeding, as for the other branches of coffee culture, cheap labour is necessary. Weeding cost our good friend, Mr. Costello, the real pioneer of coffee in Queensland, at the rate of £20 per acre! Of course that expenditure on a large scale would never pay, and a proper system of regular weeding would render it unnecessary. We met Mr. Costello on a sugar estate which he superintended, but his patch of coffee, lying a dozen miles away, we were unable to visit. From our inspection, however, of branches on which leaves had yellowed, which Mr. Costello sent for, we were able to say that the dread fungus had not then affected the trees. But how long will it be absent if coffee is cultivated on a large scale in Queensland? We should fear disease and also the effects not only of drought but of frost, from which sugar, even within the tropics, often suffers. While the larger portion of the estates in the Mackay district are exempt, a plantation opened by a Mr. Jack at some distance and at a higher elevation had a crop destroyed at its commencement. Of course a crop of canes, if injured by frost, can still be utilized and if a crop is destroyed it can be replaced. Frost affecting coffee is a much more serious evil.

The *Queenslander* in noticing the unusual weather, distinguished by a heavy fall of snow, wrote on August 12th:—

"The effect of this exceptional weather has not on the

* Bonwick states that "Rice, both on flooded and dry soil does well; there are twenty varieties known."

whole been injurious. In some places the sugar cane has suffered and alarmists have declared that there will in those places be no crop next year. The districts so affected are, however, comparatively small in extent and few in number, and a warm spring, now setting in, will probably remedy any mischief done. Against the pessimist view of the matter there is also to be set the great extent of new country, both north and south, being cleared and planted for next season, and the sugar crop now being crushed is turning out very well."

A full account of Mr. Costello's coffee experiment appears in the *Mackay Standard* of July 21st, from which we quote as follows :—

"The pioneer of the Coffee Industry, and we believe it will become in this district of sufficient importance to be ranked as an industry, is undoubtedly Mr. J. Costello, of Millicent. Although, prior to the date of that gentleman's settlement in this district, coffee plants had been raised, and in fact coffee had been manufactured, in small quantities, yet Mr. Costello was the first person to take up the business of coffee growing upon such a scale as to test its suitability to the climate and soil of the Mackay district. The work which was before Mr. Costello in his experimental venture was by no means a light one because he was not possessed of the ample means which would have rendered a trial of this crop an easy matter, and the present result of his labors at Millicent speaks volumes for the energy and pertinacity with which he stood by his pet project and has eventually overcome difficulties before which many less determined men would have succumbed. In his capacity of manager of a sugar estate, it has only been at rare intervals that he has been at liberty to visit his property at Millicent, which is situated at a distance of about 12 miles from town, on the North side. Here, however, he has managed to develop a property which, while it is particularly interesting as the pioneer coffee plantation of the district, we sincerely hope, as we honestly believe, is destined to become very profitable in the not distant future. Commencing operations by cutting down and clearing the scrub from the high ridges on his farm, he was only able during the first season, (nearly five years ago,) to plant a small number of trees which he had raised in boxes in his garden at the plantation which he was then managing. With little other knowledge than that acquired by reading, the first few years' experience of the best mode of culture of the coffee plant, was necessarily experimental and thoroughly practical; and it is gratifying to remark that the results of Mr. Costello's labors have been satisfactory. During the second year, an area of 15 acres was planted with coffee, and at the present time we should estimate that there are fully 12 acres growing well. To account for the reduced area, we may explain that in the first instance fifteen acres were planted, but before the trees had reached any great height they were subjected to attacks from scrub wallaby and other vermin to such an extent as to render it quite a question whether it would be wise to throw up the project altogether. Not daunted, however, with this reverse, Mr. Costello continued to replant and supply the blanks at the same time taking such precautions as he was able to prevent a recurrence of the attacks. Instead of attempting to enlarge the area under crop. Mr. Costello's efforts have been directed to completing so far as lay in his power the planting of the area first cleared and the result at present is that making due allowance for blanks and young plants, we may estimate that there are at present about 12 acres of coffee plants between three and four years old. At the time this enterprise was undertaken there seemed little probability of a sugar mill being erected within such a distance of Millicent as would render it desirable to plant cane, and hence the attention of the proprietor was directed to such products as might be likely to yield a fair return in future, and coffee was the one on which the owner decided. The system of planting adopted here was to place the rows at a distance of eight feet apart, and the trees are set six feet apart in the rows. At the present time the primaries are interlocking in the rows, and within another year they will do so between the rows. The trees have been of course regularly pruned and topped, and they present a very different appearance to the shrubby trees which we are accustomed to see in gardens. The plants are topped according to circumstances, such as situation, and exposure or aspect, and the average height we may place at two feet six inches. The varieties grown at Millicent are Mocha, Arabica, and Liberian, and it is remarked that the latter do not make so much growth in a given time as the former varieties. Millicent has during the last season been visited by a number of gentlemen whose experiences in Ceylon and other parts of the world entitle them to express an opinion on the subject of coffee-growing, and their reports as to the general appearance of the coffee, are such as to render Mr. Costello satisfied with his prospects of future success. The original plants nearly five years old, are loaded with the cherries, and are calculated to give a return at the rate of 12 cwt to the acre, and it is to be regretted that their number is very small. The bulk of the crop, which is between 3 and 4 years old, is estimated to give from 5 to 8 cwt. to the acre, and this, for young trees, we understand, is a highly satisfactory yield. It is probable, therefore, that the crop for this year will not fall far short of three tons, and although this will appear a small amount, yet as practically the first crop of coffee grown in this locality it is worthy of more than passing notice. The soil on which the coffee is grown is a deep chocolate, with plenty of stones intermixed, such as may be found in all the scrubs of this district in great quantities. It is by no means uncommon for coffee growers from others countries to declare that particular soils and elevations are essential to successful coffee growing, but a visit to Millicent has satisfied many of these gentlemen that the specialities considered necessary in other countries do not apply in this district. The maiden crop taken off last year by Mr. Costello was prepared and manufactured by such means as his ingenuity suggested, and having tasted the manufactured article we can conscientiously assert that it is as fine a sample of coffee as we ever had the pleasure of drinking. Mr. Costello is importing from Ceylon, for his coming crop, a pulping machine, and if, as we believe he will be, he is able to place three tons of coffee, such as we tasted, in the Queensland market the lovers of this beverage will be fortunate in having the opportunity of securing for themselves a supply of probably the best and purest coffee ever offered to the public in this colony. That Mr. Costello will succeed, as we think we have shown he deserves to do, will be the wish of every person interested in agriculture in Queensland and we can only express the hope that his success may lead to the establishment in tropical Queensland of an industry which for importance will rank second only to that of sugar."

It thus appears that coffee will grow and fruit in Northern Queensland, but it remains to be proved if on a large scale, it will pay. Not certainly if cheap Indian or Ceylon labour is excluded. And if, with Ceylon labour the leaf disease is introduced, it will be a bad lookout. Besides weeds it will be seen that the serious pest of animal vermin has to be contended with. As settlement advances, however, the wallabies (small kangaroos) and other marsupials will disappear, the fur and flesh being of some value. Ceylon planters will, no doubt, fully try experiments, with coffee in Queensland,

but they are not likely to adopt such wide planting and such short topping as Mr. Costello seems to have resorted to. Even when topped to 2½ feet, trees must be in good soil, when their primaries meet at a planting distance of 8 × 6 feet By "north side" in the account is meant the north side of the Pioneer river, and it is a curious fact that frost does more harm to plantations on the north side of Queensland rivers than on the south Nothing is said of frost, however, as affecting Mr. Costello's experimental patch of coffee. It would seem as if Liberian coffee is likely to flourish better farther north than the Mackay district. Deep chocolate coloured soil, intermixed with stones, is just what suits coffee, and the rainfall of the Mackay district fairly suits tea as well as sugar. The process will probably be, if the inflow of labour is permitted, to cultivate the flatter portions of the valley of the Pioneer with sugar, carrying coffee culture up the hilly country which stretches away from its banks and towards its sources.

After the above had been placed in the hands of the printer we received a letter written by a Ceylon planter, who has been travelling through the Australian colonies, to a friend in Ceylon. The writer followed our own route through the districts of Mackay and the Burdekin delta. Like us he had the good fortune to meet Mr. Costello, and, as a curious enough instance of "history repeating itself," we may note that as to us Mr. Costello deprecated the over-sanguine account of his coffee experiment which had been published, so on this occasion he told his Ceylon planter visitor that "the beans did not fill out properly." With his Ceylon experience, the gentleman whose letter we are referring to declares himself to be "pretty certain that between Townsville and Mackay there is no suitable land." After adding what Mr. Costello said about his beans not filling out properly, the writer gives the following:—"My advice to any one is to have nothing to do with coffee; it is too uncertain a crop altogether, and requires too many congenial conditions." The advice ought to be duly weighed, but if coffee will not succeed in the region between Townsville and Mackay, we suspect climate will be more at fault than soil. As a general rule the proper zone for coffee is 15° on each side of the equator, with a rainfall of about 70 to 100 inches. As Mackay is 21° south of the equator, and even Townsville is not nearer the line than 19°, it is probable that the region for coffee will be the northern peninsula which separates the Gulf of Carpentaria from Torres Straits. The hill ranges ought to be explored to ascertain the conditions of soil and climate. As far as rainfall is concerned Hinchinbrook Island attracted our attention as a fitting scene for an experiment in coffee, but, alas! it is "a noble cone of granite, 2,500 feet high." There is much granite (auriferous) and too much sandstone, but there is also much good soil; without a plentiful and cheap supply of labour, however, not only is it useless to talk of coffee, but sugar culture must come to a standstill in Queensland and Northern Australia.

Our remarks have extended already to such a length, that we defer our notice of sugar culture for another article.

To the above article from the *Mackay Standard*, we add the following from the *Queenslander*:—

"Coffee is one of the things which bids fair to be one of Queensland's products, and that before long. Java Brazil, and India—more particularly Ceylon are growing it largely, and find it a very remunerative crop but of late years an enemy belonging to the insect world [*Hemileia vastatrix* is a fungus.—ED. C. O.] has given the planters no end of trouble, besides heavy losses, by attacking the leaves of the trees, and thus injuring them in a vital part. Measures one after another are being devised and tried to rout the enemy, but it is found that when any of these means answers the intention it only drives the marauders back into the jungle, and it is now largely held that the invaders came from the jungle to the plantations at the first. Our readers will remember that some months back a sample of coffee from Liberian coffee trees grown on the Herbert River, Queensland, was sent down to the curator of the Botanic Gardens, Brisbane, who declared the sample superior to the original seed which came from Ceylon. Similar testimony has recently been borne by Ceylon men themselves with reference to coffee grown at Mackay; so that we have every reason to believe that, with the proper amount of capital, enterprize, and spirit, Queensland coffee, as well as Queensland sugar, may soon become a familiar household word."

Again, new country now being settled and watered by the rivers, Tweed, Richmond and Clarence is said to be eminently adapted for sugar cultivation in some parts, and for coffee in others. We should imagine sugar to be the more likely to pay, but we see:—

"As proof that coffee can be grown successfully on the high lands around the Tweed, there are many healthy, vigorous, and fruitful specimens to be seen in different localities there, grown merely by way of experiment, and fulfilling their end perfectly. On the lands at Cudgen, sold by Messrs. Guilfoyle to Messrs. Robb and Co., of Melbourne, are some tall specimens fully 8 ft. or 9 ft. high, laden with berries large in size and approaching maturity. the trees being evidently untouched by frost. Mr. Thos. Brady, of Anthony, also has a few good specimens, but they do not show to advantage, being mostly grown under the shade of strong and luxuriant clumps of bananas. These, as might be expected under such conditions, are not so fruitful, and run more to wood and leaf than they should do. While very young, shelter of some kind is serviceable to the coffee plant, when the shrubs are old enough to bear, they require, in common with all other fruit-bearing trees, perfect access for light and air to ripen the wood, or they cannot set for fruit except very sparingly. In old coffee countries, moreover, the coffee shrub is always kept low and stocky, so that the branches may be within easy reach of the gatherer, and, as the work is well suited for women and children, 5 ft. is about as high as they should be allowed to grow."

THE ASSAY OF CINCHONA.

(From the *Chemist and Druggist.*)

Dr. Squibb, in his usual painstaking and laborious manner, contributes a paper in his "Ephemeris" on "Assays of Cinchona." His method is one intended to be followed by the practical pharmacist who may wish to estimate cinchona by means which do not present too great manipulative difficulties. The point aimed at was complete exhaustion, bearing in mind that different samples of bark differ very much indeed in structure, and, therefore, in accessibility to the exhausting menstruum. Some are soft and spongy, easily exhausted with a small quantity of liquid in a short time, while others are hard and compact, and require both more liquid and longer digestion. This difference in the facility with which different cinchonas are exhausted has been too much overlooked, and may have caused the disagreement between Drs. Biel and De Vrij who, working by the same process, advised the former a digestion of four hours and the latter of one hour as sufficient.

Dr. Squibb's process is based on the fact that amylic alcohol freely dissolves all the alkaloids of cinchona barks, but does not dissolve the salts of those alkaloids, and that it dissolves much less of the colouring matter than other solvents; the outline of the

method is to break up the natural salts of the alkaloid in the bark and fix the colouring matters by lime in excess. The free alkaloids are then extracted with amylic alcohol, ether being added to facilitate the percolation and filtration. The alkaloids are coninto salts, and thus got out of the amylic alcohol verted into a watery solution. From this they are precipitated in the presence of chloroform, which dissolves them freely. Finally the chloroform is evaporated off, and the residue weighed as anhydrous alkaloids. The various steps of the process are then minutely detailed.

The digestion and shaking with amylic alcohol dissolves all the alkaloids present, and dissolves very little besides; but a portion of the solution remains absorbed by the spongy character of the particles. Such portions can be percolated out on a filter with amylic alcohol, and without ether, but the filtration is tedious and troublesome. By diluting the alcohol with about three times its volume of stronger ether, it is rendered very manageable, and the filtrations and washings are accomplished in about an hour, leaving the residue practically exhausted. If this solution be evaporated spontaneously, or by a water-bath, it creeps over the edges of the capsule badly; but if boiled down in a flask in a water bath, as soon as the ether is driven off the remainder has no tendency to creep over. Care must be taken that the ether vapour does not catch fire.

The alkaloids are washed out from the amylic solution as acid oxalates, being thus freed from waxy and fatty matters; three washings are required. The solution being concentrated, the alkaloids are precipitated in the presence of pure, not commercial, chloroform. Normal solution of sodium is added to ensure precipitation complete to an alkaline reaction, yet without sufficient excess of sodium to hold the alkaloids from the chloroform. A wet filter is an efficient means of separating the chloroform, for not one particle of it passes, while the watery solution of sodium oxalate goes through to the last drop.

In the same way the chloroform may be separated by a chloroform-wetted filter, all impurities being left behind.

A GUM FOREST.—Mr. O'Neill, H. B. M.'s Consul at Mozambique, has recently reported to the Foreign Office that from Mr. James Heathcote, of Inhambane (who was employed by him for the recovery of the body of the late Captain Wybrants), he has received information of the discovery of a considerable tract of copal forest. Mr. Heathcote writes:—"The forest where I obtained this gum, of which I send you specimens (I have collected 6 tons) is fully 200 miles long. It is a belt which runs parallel with the coast, and is midway between the coast and the first range of mountains. From Inhambane it is nearly 100 miles to get right into it." The distance of the forest from Inhambane is rather great, and may retard its being opened up; but its discovery adds to the known wealth of the district, and a new export to the place. Mr. Heathcote points out the following curious coincidence, and although it may not be the first time that attention has been drawn to it, the Consul mentions it:—"The native name of this gum is 'Stakate' and 'Staka.' The Zulu name for gum is 'Intblaka.' The name 'Stacte,' mentioned in Exodus xxx 34 (this is believed to be the gum of the Storua tree, *Styrax officinale*), would be pronounced as the above native name. The tree dominates over all, and standing in any place overlooking the forest, you see here and there trees growing as if were in a hayfield. The gum has a beautiful odour if pounded and burnt, also if boiled in a pot of water." The ordinary gum copal tree of the mainland of Zanzibar and Mozambique, though as a rule lofty, is by no means of the striking stature indicated by Mr. Heathcote's comparison.—*Public Opinion.*

THE COMING COFFEE CROP in Southern India is evidently going to be a good one, if we may judge from the number of orders for pulpers and other machinery received at Colombo recently.—*M. Mail.*

RUBBERS.—Dr. Trimen brings back a most encouraging account of the extent to which indiarubber is in demand: the manufacturers will take all the raw produce that can be sent to them, and numerous new uses for the article could be found, if only rubber were more plentiful and cheaper. On the other hand, in Ceylon, the plants are flourishing amain and may be expected to run wild with tea and lantana—so well-fitted is the climate for them.

UTACAMUND.—The extent to which the Melanoxylon has been eradicated is apparent from the scanty show in the station of the golden blossom of this variety of Australian tree. In August it usually bursts into profuse bloom and the trees are a mass of blossom with a strong though not disagreeable odour. In a few years, we may hope to see it disappear altogether if house owners continue to remove it as persistently as they have done of late years.—*South of India Observer.*

MYSORE (MUNZERABAD), 1st Sept.—Since the first week of August, weather has been fine here. Only some 18 inches of rain have fallen for the month, but we had a great deal too much of it in July when 97·08 in. fell, and June with 50·49. I would suggest your fixing a rather stronger wrapper around the *T. A.* In the last two numbers they were torn to ribbons. It was scarcely possible to read the address on one of them, and I fear in consequence some day I may have to lament its non-arrival from the impossibility of knowing in the post-office to whom it is directed. The more I see of the disease, or whatever it may be that has affected my calisayas both "Ledger" and "Verdi," before pricking out, the less I can think it is due to minute snails, as I saw mentioned in a late number of the *T. A.* Reading the article upon orange culture in August number (on the right hand column of page 119), I was struck with the idea that the "fungus of the cutting bench" seemed a better explanation, if such is possible, than any other theory I have heard started on the subject, as I have noticed the surface sand in seedling boxes adhering together with a "spider-web-like substance" where the plants were dying off.

FRUITS AND VEGETABLES are "in season" just now in and around Kandy: the market teems with them; and loads of them are carried along the roads for sale. Oranges sell at a cent each, and a hundred good limes can be had for six cents. The capabilities of the soil are such that a good trade should be established between Colombo and Kandy in fruits and vegetables of all kinds. The absence of anything like systematic cultivation is what strikes one everywhere. Even the *jak* grows almost wild here and supplies the Kandyan with a staple article of his ordinary food. The appearance of paddy fields receiving but the poorest attention from the sons of the soil gives one the idea of Palestine—the land flowing with milk and honey. Really, when looking at a vast expanse of land very near Gampola on the Pussellawa road—an expanse of paddy land all glorious with green and gold, with paddy in ears and fully ripe—ready for the scythe—bending under it's own weight and having a scent peculiar to itself,—I was forcibly reminded of Genesis xxvii 27:—"See, the smell of my son is as the smell of a field which the Lord has blessed." The seasons are eminently propitious: on the other side of the road they are just preparing the land for sowing, whilst along the line you see paddy in every stage of growth. If only the hard-working cultivator of the northern peninsula could be induced to settle here and till the land, Ceylon should once more be what it it was in ancient times, the "Eden of the eastern wave."—*Cor.*

Correspondence.

To the Editor of the Ceylon Observer.

PEELING CINCHONA BARK.

September 12th, 1882.

DEAR SIR,—Now that Mr. Gore's cinchona peeler is being used to a considerable extent, would some of your readers who have had it in use give the public the benefit of their experience, with regard to the quantity harvested per diem, by each cooly, or, that is to say, the number of pounds in all, that, say, 10 coolies could collect: some carrying the boughs, etc. to the machine, and the rest peeling?—Yours faithfully, KANIK.

WHAT AILS OUR COFFEE TREES?

September 5th, 1882.

DEAR SIR,—In attempting to ascertain the reason of the unproductiveness of coffee in Ceylon, apart from leaf-disease, a writer, under the *nom de plume* of "W.," leads us into a wide field of speculation. These speculations have given rise to criticisms by several writers, among which criticisms is a leader by your able pen, guided by a mind stored with experience even greater than that of "W." himself. [Not in regard to the cultivation of coffee!—ED.]

The importance of the subject, I trust, will be a sufficient excuse for my apparent presumption in entering the lists with such champions. When we consider the issue at stake—when we consider that the cultivation or abandonment of 250,000 acres (see your note to my former letter) is to be eventually decided by the continuance or disappearance of causes prejudicially fatal—I think that it will be admitted that the subject should receive full ventilation. In groping about for "occult" or "inscrutable" causes, would it not be wise to compare our coffee, *not* with other products, but with the same product in other countries? Is it not a fact that, wherever *Hemileia* does not exist, as in the case of Brazil, these other inscrutable evils do not appear or have not the same effect, while we find that short crops invariably and inevitably result from the ravages of leaf-disease?

I will go over "W."'s line of argument. He begins in his first letter thus:—"First: Because *Hemileia* was hardly known or generally observed in 1871, when the first general disaster to our crops occurred, there is clear proof that adverse conditions had previously set in, and that the fruit-bearing powers of our coffee-trees were already seriously impaired before *Hemileia* could have had any material or general influence." In reply, I would say that, as it is admitted that the disease appeared palpably in 1869 (Nietner, a careful observer, had been familiar with it many years previously), it is but natural to suppose that its insidious effects were felt by the coffee before it had reached a very marked stage, or before its effects had generally attracted attention. I agree with "W." as to the adverse conditions existing previously to 1871, but I maintain that these were owing to leaf-disease. Put a healthy man into a malarious district, and observe the way the disease gradually saps his strength. He may take more nourishing food, or even stimulants, as he secretly feels the climate tell on him; but slowly and surely will the effects increase, even before his outward appearance or his general powers are much affected. Would it be profitable to go groping wildly as to why malaria should have that effect on man, as to what other reasons could have been at work, when doctors tell us that malaria is prejudicial to life and health?

"Second: Because the crop of 1876, one of the largest of the decade, occurred when leaf-disease was said to have attained its utmost force, therefore it is proved without doubt that there is a want of that sympathy between the ravages of the pest and the unfruitfulness of our coffee-trees, which would necessarily exist between cause and effect." Softly. Make sure of your premises first before misleading others by twisted statements. In 1875, in the month of June, you wrote "that, with a few exceptions, leaf-disease has almost entirely disappeared, or has ceased to be a source of anxiety to the planter." Again you say:—"There is every prospect in the splendid appearance of plantations all over the country of a succession of good average crops to make amends for past deficiencies.....The appearance in wood and vegetation for next year is all that could be desired." Where does the point of the argument fit in as to sympathy between the disease and short crops in the way of cause and effect? Then we find that in 1875 double the amount of manure was carried by the railway than in 1871. Would that not influence matters? We also find the rainfall more fairly distributed; the dry districts getting more and the wet less. Would that modify the virulence of the disease for the time being? According to Ward, we have reason to believe so. Then, because leaf-disease was very severely felt in 1876, does that prove that the previous mild attack had nothing to do with the big crop? Because the man in the malarious district has over-exerted himself, after feeling stronger on account of the season modifying the evil effects of malaria, and has a relapse of weakness in consequence, is it absurd to believe that the malaria will not have a greater effect on his weakened body or that it argues that malaria is not the immediate cause of his illness? Another reason for the large total of crop in 1876 would be that the large area of coffee having just come into bearing took advantage of the favourable season to bear well and thus swelled the total.

"Third: Because coffee has not been the only product in the island, or even in the world, to suffer, therefore some wider influence than that of *Hemileia* has been in operation, not in Ceylon only, but over the whole world." Is that not straining at a gnat and swallowing a camel? Leaf-disease, being purely a local instead of a constitutional disease, caused direct damage by loss of leaves, and indirect damage by diminished crops, which again breeds fresh damage, such as hampered operations in cultivation and superintendence, absolutely necessary to make up for former heavy cropping as well as to fight the constantly recurring attacks of *Hemileia*; till we are inclined like "W." to grope half-stunned for occult reasons. Why roam abroad over the continent of India, why fly with wings of fancy to the celestial kingdoms of China, or wander from Europe to the far west? Verily this is swallowing the camel; and what about the gnat? Dr. Trimen tells us what the gnat is. He says:—"Cleared of many erroneous observations and inferences, the ordinary life-history is now shown to be of extreme simplicity." The disease is simple; but the trouble arises when we come to its effects and its cure. Let me inform "W." that he will never hit it off by referring to the agricultural history of the globe, any more than the malariously affected man will do himself any good by studying the *Materia Medica*.

"Fourth. Because something affecting the fruit-bearing power and stamina of our coffee trees had preceded and invited the attack of *Hemileia* is clearly evidenced; therefore it must be this *something* and not *Hemileia* that is the *cause* of infertility, and *Hemileia*, being a fungus, preys upon coffee as a decaying organism." Now it is not fair in argument to make use of, as a settled point, what has been brought forward at an earlier stage on the same side. I think that

that is what "W." does here. Taking it for granted that his premises under his second head were unrefutable, he builds upon it his fourth argument. Therefore I refuse to take this heading into consideration, except noting what is said about "fungi preying upon decaying organisms." What does Mr. Ward say? He says:—"*The fungus injures the coffee by robbing it of food on the manufacture of which a large expenditure of energy has been employed, by occupying valuable space on the leaves, and by producing profound disturbances in the functions of the plant.*" Here is enough of injury to ruin the most vigorous of plants; and yet "W." comes with his notions about "decaying organisms." Every practical man will refuse to allow such a term to be used with regard to his once fruitful and still comparatively vigorous fields. Surely Mr. Ward has diagnosed sufficiently on the disease and patient; and he has shewn us by the above remarks what a terrible thing it is we have to do with, and yet "W." says "we blame the *Hemileia* because it is the only one we can see." There is no doubt about the visibility of it any more than there could be doubt of the illness, and the cause of the illness, when we look on the emaciated, powerless man, reduced to that state by ever-recurring a tacks of fever fed by the malaria. Are we to act against our commonsense, and refuse to reconcile what Mr. Ward tells us with what is visible to our eyes? "W." argues thus:—"Because we are unable to know *all* the laws of nature—therefore we are unable to conclude that *Hemileia* is the true cause." So, because the doctor, who is called to the fever-stricken patient, is unable to know ALL the laws of nature as discovered by medical scientific researches, therefore he is not fitted to say whether malaria causes the fever. I deny that there is anything inexplicable in exceptional trees and spots being specially favoured. I do not see that the key to the mystery lies in those sheltered nooks, any more than the key to the favourable conditions or reproductive powers of the coffee will be found swinging on the stumps of a primary on a battered, shapeless coffee tree, standing on its tiptoes in cabooky subsoil, and exposed not only to every wind that blows, but every evil that may exist. Scientific men tells us the disease came from the jungle. A man of commonsense argues that as the fuel increases so the power of the flame; therefore what was in itself a comparatively harmless fungus, kept down to small limits by limited food, yet blazed forth in steadily increasing force, as a special plant, favourable to it as a food, was extended over a large acreage. In his second letter "W." still harps on the same strain, seeking for the *primary* cause. He says:—"Coffee had covered large areas of land for 30 years, surrounded by the indegenous vegetation in which the fungus was all along latent; but it so remained until stimulated into fearful activity by some newly-acquired condition of the trees." The spread of cholera in some large city may be the result of neteorological conditions combined with contagion brought by, perhaps, one individual; but you cannot say that contagion and the disease is not the *primary* cause and only favoured by climatic influences. "W." would have us reverse this; and this is the whole gist of his argument. Also in some climates like that of Colombo, cholera is not indigenous as on the coast; so, however often you brought the contagion, it would expire as a flame in a lamp empty of oil. Now here the *conditions* are prominent—they resist the spread of the disease—whereas, in the other case, they promote the same. In which of the two are the conditions to be primarily considered? I take it in the one where they have most power. If "W." was in search of the *conditions* as favouring the spread and continuance of the disease, I could follow him; but he insists on regarding the conditions as the primary cause. Now I think we have narrowed down the question to a point. Leaf-disease has paralyzed and crippled the coffee enterprize. *Who has found a remedy?* I am satisfied that a topical specific will yet be discovered; but what about the present? The mouse gnawing at the rope has brought the whole structure about our ears. Leaf-disease weakened our trees; the trees could not bear; the planters got no returns; the trees again suffered starvation and hardships; they became still more unable to bear; planters became still more unable to help them. These are co-relative evils. Then irregularity of suitable weather; fluctuation and fall in market prices; reckless speculation; haste in extension and selection of new plantations; and undue forcing of the soil by artificial manure—combine the latter evils with the former, and you get stoppage of all manuring; nearlyall pruning; cutting down of salaries to a point of bare existence; and at the same spreading this underpaid supervision over larger areas; and so on, in all the easy stages to abandonment and chaos—were it not for *new products*. The *Rip van Winkle* of Ceylon has wakened too late. Let us leave him trying to account for changes apparent to every observant man, and find a door of hope in the watchword of planters, *new products*. Should we wake up some morning, to find *Hemileia* gone, then it will be time to renew our advances to our old love; but at present we have taken to ourselves other maidens more comely and more responsive. Those men who are leaving us may be induced again to return, if we can offer them fruitful fields instead of barrenness.

Since writing the above, I have come across the letter of "Fatal Fungus" in your issue of the 2nd instant, which bears on the question in almost the identical words I have used. I do not look on this merely as a coincidence, but as a proof that there must be some reason in the arguments.

ABERDONENSIS.

MR. HOLLOWAY ON JAK TREES, &c.

Maria, 7th Sept. 1882.

DEAR SIR,—I am surprized that your correspondent "G. W." in reply to "P. T. L." should have stated that there are in Ceylon two species of jak: one a surface feeder and another a deep feeder; whereas, in fact, we have peni-waraka, pol-waraka, han-waraka, waraka, pol-wela, diya-wela, meti-wela, kuru-kos, kurukos-waraka, kurukos-wel and hera-pila. The latter bears fruit from the roots and is only found in Jaffna, I believe. Kuru-kos is a small sweet fruit. The natives say it is difficult to distinguish jak by the foliage: they judge by the fruit. I have found some of all kinds to be surface feeders, but that need not alarm any one: any shade tree, no matter of what species, which is a surface feeder and does not allow coffee or other products to grow near it, should have an 18 inch deep and wide trench cut around it and all roots in that trench cut out, when the adjoining trees will get as vigorous as any other trees.

I quite agree with "P. T. L." that, where jaks are planted among coffee in land having a substratum of rock, the former will thrive, if the wind does not blow them down. So would all other shade trees thrive and the coffee tree die out. I cannot hold with his objection to the litter caused by the ever-dropping leaves, simply because they fill up drains: cut 4 ft. pits in your drains every 50 or 100 yards, which will catch your surface soil and leaves; clear them out whenever full: that soil is good for supply or will assist manuring.

"P. T. L." will find many of his murunga maram also surface feeders and a mere nominal shade. He will find Sooriah and croton better.

I was glad to see "W. D. B."'s letter about the good crop he has in Dimbula on manured coffee. My experience here is the same, and I can show good crop on fields from 4 to 50 years old (native or plantation trees) again this year.

I have now with me Mr. J. T. Sturm, Naturalist and Chemist: he was a pupil under Prof. Haeckel* of the Jena University, and is now learning coffee and other produce planting, &c., &c.

"G. W."'s removal of plants in pots affected with leaf-disease to another spot when in a few weeks not a speck of the fungus was to be seen on the plants is a further proof that a change of atmosphere has caused the fungus to disappear. Coffee trees can't be shifted about; so we must apply disinfectants which are at the same time good for the plants. Again, I must request planters to give a fair trial to "wood ash and lime," dusted on the trees when wet. If very much attacked, ½ basket good cattle manure well saturated with urine around the stem of the coffee tree and scatter ½ coconut shell full of lime over the manure. I warrant that the best and quickest as well as cheapest means of getting rid of leaf-disease and securing paying crops.—Yours truly,

J. HOLLOWAY.

What ails our coffee trees?—(1) the soil they live in is full of bad gas and poor; (2) the atmosphere gets impure from the gas coming out of soil (observe lower leaves always drop first); (3) want of nourishment of the proper kind and at the right time (see good crops by good cultivation); (4) want of purified atmosphere and tonic to the leaves when first attacked with leaf-disease (lime purifies and ashes tonic).—J. H.

[Coffee on virgin soil of good quality has been no more exempt from leaf-disease than that grown on worn-out soil. What evidence can Mr. Holloway adduce for his bad gas theory, beyond the inconclusive fact that the lower leaves wither first?—ED.]

INSECTS FEEDING ON THE COFFEE FUNGUS.

Badulla, Sept. 9th 1882.

DEAR SIR,—Thinking that a new trait in leaf-disease has been discovered by me a few weeks back, I now send by tappal a matchbox filled with diseased coffee leaves. You will observe a number of insects of all sizes apparently feeding on *H. V.*, and these are only to be found on diseased leaves and on the lower side of the leaf only: these insects are very lively, and wander about all over the leaf; consequently they may get out of the box in the transmission through the post. Should this be so, I shall be glad to send you more, as they can be found in thousands on all badly diseased patches. As this pest was first discovered here, would it be too much to hope that, perhaps, the cure may also come from this portion of the coffee district?—Yours faithfully, PLANTER.

[The well known Thrips, described in "Garden Pests," page 63. These small insects feed on various plants and other vegetable substances. It is very doubtful whether they will do any appreciable good in Badulla in the way of checking the speed of *hemileia*. They consume a considerable quantity of the spores of the fungus, but scatter much about the leaves. Had they not such succulent food to feed upon, they would probably attack the tender leaves and blossom of the coffee tree. Pollen is their favorite food, but they have doubtless been attracted in large numbers by the spores of the fungus. This insect attacks cinchona leaves in some districts, but does not appear to do much harm.—ED.]

* It is to be hoped Mr. Sturm is more of a gentleman than is his conceited master.—ED.

CEYLON CEARA RUBBER AND THE RECENT LONDON VALUATIONS OF THE PRODUCT.

Peradeniya, 15th September 1882.

SIR,—I send for publication a copy of a letter addressed by me to Mr. E. S. Grigson, in answer to some questions from him, arising out of Messrs. Silver's report on the samples of Ceara rubber I submitted to them.—I am, sir, yours faithfully,

HENRY TRIMEN.

R. Bot. Garden, Peradeniya, 14th Sept. 1882.

DEAR SIR,—With reference to your questions regarding the samples of Ceara rubber from the Gardens lately reported on in London, I can give the following information:

I am ignorant of the cause why some of the rubber became sticky. Nothing was mixed with the milk which was simply dried in the sun; and all came from the same 9 or 10 trees. When sending the samples to Messrs. Silver I thought it well to separate the sticky from the other, expecting there would be a difference in value; but I was not prepared for the report of the analyst. The sand was contracted by some of the milk falling on the ground round the stem.

The report shews clearly the extreme importance of careful collection.

So far as Ceara rubber is concerned, I think we get it better in tears and strings allowed to dry in the stem than by any other way at present tried. This, too, is the form in which it comes into the market from Brazil.

If this method be followed, it will be well to plant rather closely with a view to securing straight stems and discourage branching low down. The liquid milk is very liable to drip on to the ground instead of trickling down the stem, if the latter be not fairly vertical. At the same time the trees must not be so close as to draw up the stems unduly and render them spindly.

As regards the periods of collecting, I believe that this will resolve itself into a question of expense, and would vary according to circumstances. Little harm appears to be done by an exhaustive extraction of milk at one operation extending over several days. In a large plantation, no doubt tapping might be almost always going on in suitable weather, but experience must shew whether more rubber will be obtained from any individual tree during its life by partial tappings frequently repeated than by annual ones of a more exhaustive character.

The milk from young trees certainly contains a *less proportion* of caoutchouc; but the latter is, I should suppose, of equal *quality*, though requiring more drying to obtain pure. There is thus, perhaps, not any great objection to milking young plants, especially as every thing would lead one to believe that the tree cannot be a long-lived one.

I think I have answered all your queries; and, as the matter is one of general interest, I think it right to send a copy of this reply to the newspapers for public information.—I am, yours faithfully,

HENRY TRIMEN.

E. S. GRIGSON, Esq.

THE VALUE OF NITRATES IN PLANT LIFE.

16th Sept. 1882.

DEAR SIR,—"X."'s letter in your issue of the 13th instant seems to require some reply from me.

Referring to my letter of 15th August, my argument *in re* the loss of nitrates amounted to this:—that the loss was greatly overestimated by "X." and that it had little to do with the present infertility of coffee. "X." has covered a good sheet of paper in inferring

that I hold certain views not set forth in my letter, and arguing against them. Far be it from me to attribute no value to the nitrogen added in our manures, but what I do lay stress upon is that, there are certain circumstances in which its addition is positively injurious, in causing the trees to make wood at the expense of crop. That our trees over the greater portion of the country show such a power to clothe themselves with foliage, is, in my opinion, of itself an argument that they are not suffering from want of nitrogen, and any artificial addition of nitrogen will only help them in the same direction. The main point of my letter was that the assimilation of mineral matter must proceed hand in hand with that of the nitrogenous, otherwise the tree would not crop. Is there anything in this to lead to the inference that I place no value on nitrogen? I take it that I am a closer follower of M. Ville in advocating a higher proportion of mineral matter than of nitrogenous in manure, seeing that M. Ville considers it sufficient to return to the soil *half* the nitrogen taken away by the crop. Now seeing that, according to Hughes, the soil loses by a crop of 7 cwt. an acre only 21 lb of nitrogen, the application of 600 lb of bones or say ½ lb per tree is quite sufficient to restore the full amount of nitrogen required by the soil, and on the theory of M. Ville have as much again to go to waste without impairing its productiveness. I see no reason, therefore, why I should be in the market for beef, otherwise castor cake, so soon as "X." expects. Sufficient unto the day is the evil thereof, and as long as our oldest estates show themselves to be so abundantly supplied with nitrogen it appears to me a secondary consideration whether there is a slight waste of nitrates from the soil taking place or not.

However much our most experienced planters may be inclined to place faith in cattle manure, which "X." says is chiefly valued for the nitrogen it contains, it is probable that the more experienced they are the more often they have witnessed that cattle manure frequently puts wood only upon the trees, which is not very profitable cultivation for the proprietor of the estate. Cattle manure is not valued so much on account of its nitrogen as for the reason that it supplies plants with all the necessary elements of food in the most available form; it is chiefly deficient in phosphoric acid which should therefore be added to it artificially. The value of cattle manure depends much upon the time that it is applied; if used fresh from the shed it is of little value on account of its nitrogen, the proportion of that element being at that period but trifling, as compared with the mineral. If planters upon high-lying estates would but avail themselves of this fact and use their cattle manure straight from the shed with an addition of lime, they would find their crops considerably better than they now do by following the old custom of applying it when fully fermented. I fear that "W." is too well acquainted with vegetable physiology and the gases which plants inhale and exhale, to find much assistance in "X."'s suggestion, in the latter part of his letter, towards explaining the origin of leaf-disease. The assimilation of facts is, I should say, a more difficult process to some thinkers, than that of nitrates by the coffee tree.—Yours faithfully,

W. D. B.

COMPARISON OF THE VALUE OF CINCHONA MACHINES.

September 18th, 1882.

DEAR SIR,—In your issue of the 14th, your correspondent "Kanik" desires to know the number of pounds of bark which can be harvested with my cinchona machine, inclusive of the labour employed in collecting the twigs. Reading his letter has recalled to my mind a point on which I have often insisted, in comparing the relative efficiency of different cinchona machines. This is, that we must *not* include in our consideration the labour required to supply material for the machine. To do so inevitably vitiates the correct proportion; because the *same* number of coolies with two different machines may require a *different* number of coolies to keep them supplied, the latter number naturally increasing with the efficiency of the machine supplied. My meaning will be at once rendered clear by putting a case in figures, calling our machines No. 1 and No. 2. Let us say that, material supplied, with No. 1 machine 6 coolies yield us 360 lb of bark: and that similarly with No. 2 machine 6 coolies yield us 180 lb. Then, in the first case, we have 60 lb per man and in the second 30 lb and hence it is of course clearly proved that No. 1 is twice as good as No. 2, as an appliance. Now let us add 6 more coolies in our first case to supply twigs sufficient to give 360 lb bark. Then in our second case we shall only require, other things being equal, 3 coolies to supply twigs for 180 lb bark. We thus have 30 lb per head in the first case and 20 lb per head in the second case. But 20 is more than half of 30, and hence it is shewn that an unjust estimation of the value of the appliance itself is arrived at by the method of "Kanik."

It must in fact be remembered that the goodness of the machines employed is only one of the causes determining the whole average cost of the harvesting; that the two do not vary directly together, and that therefore it is a mistake to estimate the former by the latter. I have trespassed already too much on your valuable space in considering such a simple point. So I will only add that I think my machines will always peel what I have advertized them to peel, without any difficulty, and that I, equally with "Kanik," shall be glad to hear the reports of those who have patronized my invention.—Yours faithfully,

J. F. W. GORE.

SERICULTURE.—With the view of promoting the silk-industry in this country, the Government of India made arrangements for the supply of a small quantity of silk-worms' eggs of the univoltine variety, and offered to place at the disposal of His Excellency the Governor in Council two ounces of these eggs for experiment during next cold weather. Besides the supply they offered free of cost, Mr. Buck inquired whether His Excellency the Governor in Council would consent to purchase 1 lb of eggs in April 1883 for trial in the following year; and if so, whether the multivoltine or the univoltine variety would be preferred, and by what date the eggs will be required for hatching. The date should correspond as closely as possible with the season when the mulberry is in new leaf, *i. e.*, in or towards the close of the cold weather.—*Madras Mail.*

A CEYLON PLANTER IN JAVA.—An ex-Ceylon planter writing on 26th August says:—"We have had a fearful spell of wet weather here: out of 120 days, only 3 days without rain, and that, in bungalows made of bamboo, with mud floors, is anything but pleasant, and slightly conducive to rheumatic fever. We grow our coffee out here under a shade tree called 'dadap,' and the better and thicker the dadap grows, the better your coffee, and the larger your crop. It seems very curious after Ceylon, for one can't get the coffee to crop at all under shade there, and here it won't crop well without it. They say the wind is awful here, but, as it does not come on till January, I am unable to tell you anything about it. I was very much shocked to see the death of S. R. Aitken in your paper: I did not know he was suffering from any ailment at the time I left. Wishing you every success in the old-country, which I look on as a sort of home from out here."

Enterprize.—A scheme is on foot in which capitalists undertake to invest £10.000 in importing and breeding ostriches and cultivating wattles and olives in the Northern Territory of Australia.—*Pioneer.*

North Travancore Land Planting and Agricultural Society (Limited).—The writer of the letter on the Kannan Devan Hills in a recent issue now writes to us:—"The Society have decided to grant a commission to agents who will effect sales of land for them, and if any one would care to undertake an agency, they would hear of favourable terms by writing. Mr. A. W. Turner will gladly put up any one who may come over, and show him over the land. The journey would be a most charming excursion."

Pearl Oysters migrating from the Red Sea to the Mediterranean is a piece of news given in the *Graphic* by this mail. Can any one send us Dr. Keller's report, or is it given in substance in *Nature*?

Dr. Keller has communicated to the Swiss Geographical Society some interesting notes relative to the migration of fish by means of the Suez Canal. It was at one time predicted that the interchange of fish between the Mediterranean and the Red Sea would soon assume large proportions, but this prediction has not been fulfilled. Specimens of the smaller Mediterranean fish have been found in the Red Sea, and for some unexplained reason the fish seem to travel in that direction in preference to the other. The most interesting circumstance noted is that the pearl oyster is slowly making its way toward the Mediterranean. Its progress is slow, but it is said to be moving in large companies.

Malt Coffee.—If that new temperance beverage, malt coffee, be as strengthening and nutritious as other malted foods it will be a matter for regret should this addition to the national dietary come to harm through fiscal regulations. There are, we know, several so-called "coffees" whose disappearance would be no loss to the British public. These are, for the most part, coffee only in name, a very small portion of the fragrant berry being mixed with ingredients which have no sort of claim to public favour. Malt coffee, on the contrary, should be both wholesome and invigorating, if the constituents are what the name implies. Each is beneficial in its own way to the human constitution, and the combination ought, therefore, to improve the health of those who consume it. We assume, of course, that the article is genuine; real coffee and real malt in due proportions, without any foreign ingredient added. Such is the claim, at all events, by those who have introduced the compound, and, if it can be upheld, the new industry would seem rather to deserve State encouragement than suppression.—*Globe*, 4th Aug.

Ekman's Fibre Patent—. Mr. Thomas Christy, of Fenchurch Street, writes again:—"Mr. Leechman has had another interview with Mr Ekman with a view to determine if his patent process could be profitably employed in Ceylon upon coconut husks with a view of extracting the fibre so as to yield a commercial result. The apparatus, which consists of a cylinder for boiling the material in, and a furnace for making bi-sulphite of magnesia, is the whole plant that is necessary, of course provided anyone who is going to work it has a small steam boiler, because the fire is not put under the cylinder, but the contents of the cylinder are heated by steam. So many people ask me where the paper on which the book is printed has been made. My reply is, 'at the Ilford paper works!'"—[The paper is of excellent quality and the wood pulp is so cheap, that to prepare and export fibres hence for paper making, would be in most cases useless. But, according to Mr. Christy, Ekman's patent process will facilitate enormously the preparation of fibres from plantains, pineapples, aloes, &c., for textile purposes, the fibres for such purposes selling at high prices.—Ed.]

The Tea at present most in demand in the London market is a good thick malty liquor, with a bright copper colored infused leaf; undertermented teas with pale liquor and greenish infusion which was the fashionable tea a short time ago, now finds no buyers.—*South of India Observer.*

Shaving Cinchona.—Has any one experience extending over a longer period than three years and four shavings? We hear of a planter in a high district whose trees are renewing their bark for the fifth time—with from six to eight months between each shaving—and his experience has been an increase in quantity and largely in quality at each shaving, while only a small percentage of his trees seems to have suffered in any way.

Grafting Extraordinary: Vines on Cacti.—Dr. Taylor of "Science Gossip" writes to the *Australasian*:—"I don't know how much truth there is in the stated discovery that experiments have been made in South California which are likely to revolutionize viticulture. Grape cuttings, inserted or grafted on the trunks of cactuses, are said to flourish as vigorously as on cultivated land. If this be so, the most barren lands of tropical regions may be turned to valuable account. I mention the statement (which I have seen in an American scientific journal) for what it is worth as well as to give a hint to such of my Australians readers as may be iterested in vine culture."

Quinine: Prof. Morton on the New "Chinoline."—According to the *Oil and Drug News*, President Henry Morton, of the Stevens Institute of Technology, who has given much attention to the production of artificial quinine, was recently interviewed by a reporter and said that artificial chinoline was so much like the drug of commerce that many persons believed it to be the medicinal equivalent of quinine. If it did not prove to be fully that, there could be no doubt that the progress thus made would be advanced till it produced quinine itself. By a process of destructive distillation, chinoline could be obtained from quinine, and, with the resources of modern chemistry, it was certain that this result could be reversed. Professor Morton said that he had manufactured the artificial chinoline in his own laboratory, a few ounces at a time, until he had produced probably some three pounds in all. He had succeeded in making some minor improvements in the process, as for instance in the purification. When first made in Germany, the colorless liquid assumed a reddish-brown tint on exposure to the air, but as he now made it, the liquor remained colorless at all times. This liquid was combined with tartaric acid, and then formed bi-tartaric of chinoline. In this form, if pure, it was a white, crystalline powder, resembling commercial sulphate of quinine. Professor Morton exhibited some of this powder. It has an acrid, slightly burning taste, but the flavor is not so bitter as that of quinine, and it passes away much more quickly. A number of experiments to test the medicinal qualities of the new product have been made in Russia, Germany and America, but with no decisive result. It has been proved, however, that the artificial chinoline, when administered medicinally, has the effect of lowering the temperature, as quinine has, and that, like quinine, it is a powerful antiseptic. When asked as to the probable supply and cost of artificial chinoline, in case it should be proved the medicinal equivalent of quinine, Professor Morton replied that it could easily be manufactured in great quantities at large works erected for that purpose, and that the actual cost of its production need not exceed one dollar a pound. Inasmuch as the supply of Peruvian bark was diminishing, the great importance of a cheap inexhaustible substitute was apparent. This last statement of the Professor is certainly no borne out by the great extension which is taking place in chinona cultivation.

LIQUID FURNITURE POLISH.—Dissolve 4 ounces D. C. shellac in 2 pints alcohol, and add 2 pints of linseed oil, and 1 pint spirits turpentine. When thoroughly mixed, add 4 ounces sulphuric ether and 4 ounces aqua ammonia. This requires to be shaken when used, and is applied with a soft sponge.—*Oil and Drug News.*

THE COFFEE BERRY.—With reference to an Occasional Note in your issue of the 17th ultimo, wherein it is stated that "another new product has just been perfected by Mr. de Bavay of the Ceylon Brewery in the form of spirit which he distilled from fermented coffee berry, &c." allow me to state that there is nothing new in this for in my Hand Book to coffee planting in Southern India, published in 1864, at pages 136, '37 and '38, I have fully described the process from actual experiments, not only with the fresh coffee pulp, but also from the dried husks of the fruit in the manufacture of spirits. JOHN SHORTT.—*Madras Mail.*

MR. DELISSA, the pioneer of the sugar-planting enterprize, in the Northern Territory, was, says the *Daily Press*, a passenger from Port Darwin to North Borneo by the E. & A. steamer "Tannadice," which landed him at Sandakan. Mr. Delissa was the means of introducing the sugar-cane in the Palmerston district, and Delissaville plantation is now a very flourishing monument of his enterprize and skill. He resigned his post as manager there because the Company working it placed another gentleman unacquainted with the industry over his head. Mr. Dellissa has gone to Sandakan to take up land there to commence sugar growing, in which undertaking he is sure to succeed.—*Straits Times.*

ENEMIES OF COCOA.—A Badulla planter writes:—"I send you by this post a box containing some beetles, and should be obliged if you could inform me of their species. They are very destructive to young cocoa trees, and devour the bark greedily, but do not interfere much with the leaves. There are large numbers of them on a young cocoa clearing here, where they have done considerable damage." The insect is a weevil belonging to the family of beetles named curculionidæ, of oval shape, length 7-16ths of an inch exclusive of rostrum. Thorax and wingcases pale brown with dark brown patches and buff markings; a buff band extends across the elytra in a bent form. Legs long and robust, with large tarsi. The whole insect is clothed with small oblong scales, discernible under a low magnifying power.

COFFEE EXHIBITION IN NEW YORK.—The members of the Coffee Exchange yesterday afternoon marched to the office of the Brazilian Consul, at No. 42 Broadway, where an exhibition of Brazilian coffee was opened under the auspices of the Associação Centro da Lavoura e do Commercio, which conducted the international exhibition of Rio de Janeiro last fall, when 1,200 samples were exhibited. After the close of this exhibition the samples were divided and sent to this city, London, Paris, Vienna, and even to St. Petersburg, where it is hoped to awaken an interest in coffee which, strange to say, is not consumed in Russia. There were 200 samples in the lot exhibited in this city. The members of the Exchange went from sample to sample, discussing the merits of each. A cup of coffee was handed to each visitor. The exhibition is under the immediate supervision of Senhor Salvador de Mendonça consul general. Brazilian Chargé d'Affaires J. G. do Amaral Valente was also present. The chief objects of the exhibition are to give the New York importers a better knowledge of the qualities of coffee produced by the different states or provinces of Brazil, and if possible to encourage direct dealings between the planter and the American importer. The Brazilian consul is now preparing an account of the actual cost of producing coffee on the plantations, the estimate including the rental of the land, value of the slaves, labor, etc.—New York *Commercial Bulletin*, June 14th.

JAMAICA LABOUR.—It is a remarkable fact that whilst there is a consensus of opinion as to the necessity for a well-organized scheme of coolie immigration for Jamaica, yet whenever the construction of some great public work creates an urgent demand for labour within a certain radius of the colony, attention is immediately turned to its resources. This was notably the case a few months ago, when M. de Lesseps began work in earnest on the Panama Canal, and thousands of Jamaica negroes were drawn thither by the promise of high wages. Just now a railway is to be made in San Domingo under the auspices of some Cuban capitalists, but the Government of Cuba will not permit labourers to be engaged there for the purpose, and hence the contractors intend, it is said, to send a vessel to Jamaica to enlist men. It certainly seems parodoxical that enterprize in Jamaica should in popular belief be langnishing for want of sufficient labour, and yet at the same time it should become a source of labour-supply to its neighbours. The explanation, of course, is that the men who go on railway and canal works do not take kindly to estate work on the Blue Mountains.—*Planters' Gazette.*

BLUE GUM OIL A SUBSTITUTE FOR CARBOLIC ACID.—A Planter writes:—"The enclosed is from a recent list of new medicines bythe big London Chemists, Burgoyne & Co. Can we not turn our gum trees in Ceylon into some use. How should the oil be extracted and how should or can an extract be made of the leaves?" The extract is as follows:—"Eucalyptus Globulus.—The oil of Eucalyptus Globulus, as a substitute for carbolic acid, has been much advocated of late. It is a most valuable antiseptic, and has obtained the happiest results in malarial fevers, as well as in bronchial catarrh. Professor Lister is of opinion that the Eucalyptus Globulus should supersede carbolic acid as an antiseptic because of its harmless nature. It contains—(1) Eucalyptic Acid; (2) a volatile oil; (3) a resin which has an acid reaction; (4) Eucalyptin, a bitter crystalline substance soluble in ether and alcohol; (5) a yellow resin of bitter taste; (6) a white body crystallising in needles called Eucalyptol. There are other elements, but these are the most important. Eucalyptus has been found by Mosler to have a marked effect in reducing the volume of the spleen. By using an extract of Eucalyptus leaves the spleen decreased in all its dimensions."

THE NEED FOR A COFFEE SYNDICATE in London cannot be doubted, and we are pleased to see that the Travancore Planters' Association has taken up the matter. One of the results—a most important one—of the Calcutta Tea Syndicate has been the opening up of new markets for Indian tea, first in Australia and New Zealand, and more recently in America. There is no reason why the cultivators of the fragrant berry should not take united action to protect their interests, as the tea planters and merchants have. Had there been a coffee Syndicate, with a representative committee in London, there would in all probability have been much less delay in prevailing upon the Home Government to take steps to prevent such shameful adulteration as existed before Messrs. Pasteur and Dickson took up the matter. They, by sheer force of fact and argument, brought the Government to a sense of the injustice which was being done to the coffee enterprize by the extensive and unprincipled system of adulteration of coffee by mixtures of roasted dates, figs, beans, &c. The formation of a coffee syndicate was suggested to us by planters sometime ago, but we believe the subject has never been taken up seriously by any of the planters' associations till now. We should think that the associations of India and Ceylon will be ready to act with the Travancore Planters' Association in an endeavour to form a Coffee Syndicate "to watch, protect, and further the interests of the coffee enterprize generally."—*M. Mail.*

IGUANA OIL.

(TO THE EDITOR OF THE "AUSTRALASIAN.")

SIR,—Iguana oil is good for the growth of hair. I may inform you that on our station, Murrumbill, North Queensland, the shearers and boundary riders use it occasionally, about twice a week, for the cure of scurf, which is prevalent in our district, and it has also the effect of making the hair thick and glossy. The way they make the oil is to take the fat from the iguana, and render it down in an earthenware jar, and perfume it with oil of lemon. I shall be glad to know through your columns how your correspondent gets on, as I return home on the 3rd of January.

E. MURRAY NAUGHTON.

Murrumbill, North Queensland.

DESTROYING TREE STUMPS.

SIR,—Knowing the difficulties met with by selectors in clearing their land of stumps for cultivation, I append the following, which I take from the *Family Reader* of January 26, 1878, No. 356, for insertion.

Dec. 4. A WELL-WISHER OF SELECTORS.

"A very simple process is employed in America for freeing woodland newly brought into cultivation from the stumps of trees. A hole some 2in. in diameter and 18in. deep is bored in the stump about autumn, filled with a concentrated solution of saltpetre, and closed with a plug. In the following spring a pint or so of petroleum is poured into the same hole, and set on fire. During the course of the winter the saltpetre solution has penetrated every portion of the stump, so that not only this, but also the roots, are thoroughly burnt out. The ash is left *in situ*, and forms a valuable manure." I imagine, failing petroleum, kerosene would act in the same manner.

[Although this recipe has been given several times, we accede to our correspondent's request, in the hope that the plan may prove useful to readers who may not have seen it before. We shall be glad to hear from those who have tried it the results of their experiences with our gum trees; the trees principally thus dealt with in America are likely to be firs.—ED. *Australasian.*]

IGUANAS AS VERMIN DESTROYERS.

SIR,—In some of your recent issues I have seen inquiries made as to the possibility of finding a market for iguana oil. This leads me to suppose that some persons are killing them wholesale, or are prepared to do so in the event of a market for the oil being forthcoming. Now it has been proved that iguanas, during the summer months, destroy countless numbers of young rabbits in the burrows. It is only the other day that a gentleman, whose station is overrun with the vermin, expressed an opinion that during the hot weather the increase of rabbits in sandy country was almost checked by the raids made on their young by the iguanas, and that for six months in the year one iguana would kill as many rabbits as two men would employed in digging them out. In the face of such a statement from a reliable source, it is to be deplored that iguanas should be generally killed wherever seen. I have given strict instructions to my men never to interfere with them, and hope that by now drawing attention to the subject through your wide-circulating columns, I may induce others interested to do likewise.

SPINNIFEX.

[Iguanas are also destroyers of snakes; their value in that capacity alone should preserve them from injury by man.—ED. "*Australasian.*"]

THE LAYERING OF SHRUBS.

Layering is the simplest of all methods of propagating, and one which the amatuer who wishes to multiply his shrubs, and is without the facilities afforded by a propagating house, most frequently resorts to. Indeed there are some shrubs that can with difficulty be propagated in any other manner; the Dutchman's Pipe (*Aristolochia*), for example, is treated in this manner in the nurseries, and the charming little Garland Flower (*Daphne Cneorum*), so difficult to grow from cuttings, roots readily when layered. As stated last month, there are some varieties of the Grape that can only be propagated in this manner, and the usual method of layering the vine was illustrated on page 292.

This method is easy with those shrubs that form branches so near the ground as to allow them to be bent down sufficiently to admit of the burying of a portion a few inches below the surface. After the layer is made, care must be taken that the soil does not become dry. A few flat stones placed on the surface will prevent this. Where it is desirable to layer a shrub, the branches of which are too high for the purpose, a flower-pot may be cut in two, lengthwise, using an old saw; then, if need-be, enlarge the drainage hole, and place the pot around the branch, wiring the two halves together. The pot is then filled with good soil, and, if necessary, supported by a stake. Of course the earth must be kept constantly moist. It is well to "ring" or remove a portion of bark from the stem.—*American Agriculturist.*

CHEAP EXTRACT OF VANILLA.

C. A. McG., Jeanerette, La.—Will you please be kind enough to give formula for making extract of vanilla from tonka beans, and oblige?

Answer.—Extract of vanilla cannot be made from tonka beans, but an imitation vanilla extract, which we suppose is what you mean, may be made as follows:—

Tonka beans	7 ounces.
Brown sugar	2 „
Water	24 „
Alcohol, 95 per cent...	40 „
Caramel	q. s. to color.

Cut the beans up fine and mix them with the sugar, bruise in an iron mortar together; then add one pound of pure white sand. When thoroughly incorporated, tranfer to a percolator, and after mixing the alcohol and water pour it gradually on. An extract that will give better satisfaction, and that ought to be cheap enough at the present price of vanilla beans, may be made of the following ingredients, treated in the same manner as the former:—

Vanilla beans	1½ ounces.
Tonka beans	4 „
Brown sugar	2 „
Water...	24 „
Alcohol, 95 per cent...	40 „
Coloring	q. s.

SAWDUST FOR BEDDING.

TO THE EDITOR OF THE "JOURNAL OF FORESTRY."

SIR,—In reply to "Subscriber's" letter in last month's *Journal of Forestry* (p. 824), regarding sawdust as a substitute for straw for bedding, I beg to state my experience. We have used it for a number of years at Taymouth as bedding for the dairy-cows, the horses at home farm and young horses in loose boxes, and never found that it injured the animals in the least. We use the dust of all kinds of wood (fir among the rest) sawn at the estate sawmill, and prefer it *dry*. The wet bedding *only* is removed from the stables, and byres daily, and mixed in the dung-pit. It absorbs a large quantity of liquid manure. We have used this manure for root crops and for top-dressing pasture lands, and always found it produced good crops. Care, however, must be taken to remove as little dry sawdust from the stalls as possible unless there is enough liquid manure in the pit to soak it thoroughly.

WM. DUNN.

Mains of Kenmore, Aberfeldy, N.B.

USE OF CARBOLIC ACID IN FORESTRY AND NURSERY GARDENS.

SIR,—With reference to the notice in the *Journal of Forestry* for March, 1882, I think it well to call attention to the fact that the employment of carbolic acid—as it might naturally be supposed—is in a high degree detrimental to the growth of seeds.

The experiments which I made last autumn, purposely, in a room of low temperature, gave the results recorded

below. The germination proceeded slowly, and I should have continued my observations longer if the seeds in sections number 10 and 12 had not been devoured by mice.

I think that the knowledge of this experiment may preserve many readers of your *Journal*, who might be tempted to steep their seeds in carbolic acid before sowing them, from serious loss.

a. Scotch Fir Seeds of One Year.

	Without carbolic acid.	10 minutes in a solution of 1 per cent.	10 minutes in a solution of 5 per cent.	1 hour in a solution of 5 per cent.
	Per cent.	Per cent.	Per cent.	Per cent.
In blotting paper.....	(1) 50	(4) 29	(7) 0	(10) 0
In Nobbe's apparatus.	(2) 59	(5) 18	(8) 10	(11) 0
In flannel	(3) 56	(6) 53	(9) 23	(12) 23

Red Clover of One Year.

In Nobbe's apparatus.	(14) 84	(17) 0	(20) 0	——
In flannel	(15) 86	(18) 73	(21) 21	——

Duration of the experiments, four weeks.

Darmstadt GUSTAV HICKLER.

THE USE OF CARBOLIC ACID IN FORESTRY.*

Carbolic acid being antiseptic, is used for preserving timber; but it is to another of its uses that attention is here called. Carbolic acid affords to plants a most effective protection from their enemies. Gardeners have discovered that seeds (peas, beans, maize, &c.) which before putting into the ground have been kept rather less than twenty-four hours in a weak mixture of carbolic acid and water, will not be meddled with by worms, mice, moles, or other enemies. The seeds themselves are said to receive no injury from this treatment. A tree painted with the same weak mixture will not be approached by rabbits. This also has been proved by experiment. In houses rats, mice, and vermin may be driven away by the smell of carbolic acid.

The idea suggests itself that in forest economy also this little-noted property of carbolic acid should be utilized, There is no reason why tree seeds should not likewise be treated with weak acid to protect them against the attacks of mice and birds; at worst no diminution of germinative power would be caused by this process.

To prevent birds feeding on tree seeds, experiments have recently been made with red minium, and the seeds before being sown were coloured with this substance. This remedy, however, seems to have had doubtful success, as can be gathered from *Danckelmann's Zeitschrift fuer Forst und Jagdwesen*, (pp. 455 and 576 of the 1880 set), although a more recent writer (p. 637) tells of favourable results.

At all events, to steep seeds in weak carbolic acid is simpler than to colour them with vermilion, and the expense can be no hindrance, seeing that crude carbolic acid can be obtained either from the chemist or grocer at a cheap rate. For these reasons this remedy is recommended to the members of the forester's profession to be employed experimentally.

Perhaps also nursery plants and valuable young trees might be protected from the destructive bites of hares and roe deer, if from time to time the plants were watered. —*Journal of Forestry.*

LIQUID MANURE.

TO THE EDITOR OF THE "QUEENSLANDER."

Can I make liquid manure from the scrapings of my fowl-house? If so, please explain the method of preparing it. E. WILLIETT.

Brisbane, January 27.

[Stir a bushel of scrapings into fifty gallons of water. Let it settle for a day; then use the clear liquid.]

TO DESTROY SMALL BLACK ANTS.

These little pests are in the habit of over-running peoples' houses to an extent which is excessively annoying. I have discovered a remedy in an American publication, and that is—Take a white china plate and spread a thin covering of common lard over it; place it on the floor or shelf infested by the troublesome insects and you will be pleased with the result. Stirring them up every morning is all that is required to set the trap again. W. FARAWAY.

Stoney Creek, February 6.

GAS LIME.

Can you give me any information about gas lime? What chemical change does lime undergo at the gas works? What is the difference in application and effect of gas lime as compared with the ordinary lime used in farming?—Yours &c., C. HARTMANN.

Range Nursery, Toowoomba, January 31.

[Lime is merely a means of converting manure into living plants. The precise nature of the chemical effect produced in soils by the use of lime has always been a subject of uncertainty. But as we know the effect produced *out* of the soil by its agency, it is usual to consider that it acts in the same manner on substances in the soil. It is thus not a manure of itself, but it acts upon inert vegetable humus, causes it to enter into union with oxygen, giving rise to humic acid This latter unites with lime to produce soluble humates, and as these salts yield nourishment to plants, it is evident that lime is advantageous to them. It also neutralises the acid properties of some soils. The effects of burning upon lime consist not merely in the expulsion of the carbonic acid of the stone, but in the production of a variable quantity of gypsum and silicate of lime. Gas lime is produced as follows:—Slacked lime is regularly spread on perforated iron shelves in a large cast-iron box. The gas passes through this lime, which deprives it of its sulphuretted hydrogen. The gas lime as it leaves the purifier is a mixture of sulphur of calcium and a certain quantity of unneutralised or caustic lime. Alkaline sulphurets are injurious to vegetation, and for this reason gas lime should never be applied in its fresh state. By exposure to the air, the sulphuret of calcium speedily absorbs oxygen, and becomes sulphate of lime or gypsum. As a manure the gas lime supplies gypsum and sulphur, and hence may be applied in the same manner as gypsum.]

INTERDEPENDENCE OF PLANTS AND ANIMALS.

Few, perhaps, know that a certain little gall fly (Cynips) of Asia Minor decides on the existence of tens of thousands of human beings. As our clippers and steamers carry the produce of the land from continent to continent, so these tiny sailors of the air carry the fertilising pollen from the male to the female flowers of the fig tree. Without pollen there come no figs, and consequently on the activity and number of the gnats depends the productiveness of these trees. The fruit of the fig is not, as in most other cases, a pericarp enveloping the seed, but a common calyx or receptacle which encloses the flowers. In the centre of this receptacle the cavity is lined with a multitude of flowers, the male and female blossoms being on distinct plants. The medium of communication, to these flowers is only a small aperture at the summit of the receptacle. Hence the access of pollen to the female blossoms is impossiblehy the ordinary means of transmission, and this is accomplished by the little gnat, which is continually fluttering about from fig to fig for the purpose of finding a suitable place in the cavity to deposit its eggs. These gnats, therefore, regulate in fact the extensive and profitable fig trade of Smyrna. A little ugly beetle of Kamschatka has, in like manner, more than once saved the entire population of the most barren part of Greenland from apparently unavoidable starvation. It is a great thief in its way, and a most fastidious gourmand moreover. Nothing will satisfy it on a long winter evening—and we must bear in mind that these evenings sometimes last five months without interruption—but a constant supply of lily bulbs. The lilies are well content with this arrangement, for being eaten comes as natural to them as to a Fiji islander; and they are, as a compensation, saved from being crowded to death in a narrow space, while those that escape the beetle shoot up vigorously the next summer

* Translated from the *Forst und Jagd Zeitung.*

in rich pastures. Still better content are the Greenlanders; for, when their last mouthful of meat and their last drop of train oil are gone, they dig up and rob the provident little beetle of its carefully-hoarded treasures, and, by its aid, manage to live until another season.—*Scientific American.*

THE CLOVE AND PEPPER CROP OF ZANZIBAR.

The only products of the island of Zanzibar are cloves, peppers and cocoa nuts. United States Consul Bachelder writes as follows:—

The clove crop the last season, commencing in September and ending in June, can only be given from what my own knowledge enables me to say, as no statistics whatever are kept by the Sultan or any of his officers. From actual inspection, and information obtained from the natives, I estimate the last season's crop at 1,400,000 pounds; which sold at an average of $9 per 35 pounds, or $36,000. This crop was the largest gathered since the hurricane in 1872: and each year now, for some years to come, the crop will continue to increase, as new trees are continually being planted and beginning to bear. In this estimate it must not be understood is included the entire quantity of cloves exported from this place, as the entire product of the island of Pemba is brought to this market for sale and export. This crop is much larger, and was estimated the last year at 3,500,000 pounds, valued at $900,000; so that the entire clove crop of this island and Pemba reached the large quantity of 4,900,000 pounds, and brought the good sum of $1,260,000. Of this quantity there were exported to the United States 1,206,120 pounds, valued at $344,541.

Pepper, owing to the great advance in price abroad, fully equaling 100 per cent, has received a great deal more attention than formerly, and in consequence a large crop has been grown, which I estimate at 315,000 pounds, valued at $36,000. Of this, 37,000 pounds were exported to the United States, valued at $3,251.

The cocoanut growth is not of much importance, and no statement can be given of the amount or value. None are exported to America, but most all go to France, and are used in making soap.

The revenue of the island is from the customs, which are farmed out to private parties, and which might be estimated at $500,000. From an extra tax on all cloves and rubber the Sultan obtains a further sum of about $400,000. This, with a moderate revenue derived from his own clove plantations, gives him an average income yearly of, probably, $1,200,000.—*Oil and Drug News.*

DETERMINATION OF POTASH IN POTASSIUM SALTS AND POTASSIC MANURES.

According to the nature of the salt there may have to be determined potash, soda, magnesia, chlorine, sulphuric acid, nitric acid, moisture, insoluble matter, &c. The author, M. A. Rousselot, treats here merely of potash.

A. Dissolve 10 grms. in water, and make up to a litre. Take, according to the nature of the salt, 125 or 250 c.c., and introduce into a half-litre flask. Boil for a few moments, and add 20 c.c. baryta-water at 1-20th in case of a chloride, or 50 c.c. if a sulphate. Pass in a current of carbonic acid, boil for half an hour, let settle for some hours, filter into a flask marked at 500 c.c., and make up this volume with the washing-waters.

B. Take in duplicate 200 c.c. if a sulphate, or 100 c.c. if any other salt; put the portions into two porcelain capsules of 10 centimetres in diameter, add hydrochloric acid, and then 40 c.c.=2 grms. platinic chloride at 1-20th. Evaporate to dryness in the water-bath, and take up in alcohol at 69° mixed with 1-10th ether; wash by decantation with the same liquid, so as to have about 200 c.c. of filtrate.

C. Put the filter and its contents into a ½ litre flask, pour upon it boiling water in small quantities by means of a washing-bottle, until the platinum salt is completely dissolved. Heat in a large porcelain capsule (16 to 18 centimetres in diameter) about ½ litre of distilled water, and add 20 c.c.=2 grms. sodium formiate solution at 1-10th, and heat to a boil. Pour then into the capsule the solution likewise boiling, of the potassium chloro-platinate. Keep up the ebullition for a quarter of an hour, and until all escape of gas has ceased. When the liquid is clear and quite cold, filter, wash the precipitate with hot water acidulated with hydrochloric acid, and pour it finally upon the filter. Clean the sides of the capsule with a glass rod tipped with a small caoutchouc stopper, still using the acidulated water, and finally finish washing the filter with hot distilled water. The filter and its contents are dried, calcined in a small tared platinum capsule, and weighed. The net weight found after deduction of the ash of the filter is multiplied by 200 × 0·4747. We have thus at once the percentage proportion of KO in the salt analysed. This method, though somewhat long, totally eliminates the excess of barytic salt, and furnishes very accurate results.

For the determination of potash in manures the author takes 10 grms. After having ground it up in a mortar, and exhausted it completely with boiling water, he filters and makes the solution up to 1 litre. He then operates upon quantities of the liquid corresponding to 1·25 to 5 grms. of the manure, and treats with baryta-water. Then after a long boiling, at least half an hour, to expel ammonia and eliminate phosphoric and sulphuric acids, a current of carbonic acid is passed into it for half an hour. After boiling, to decompose the bicarbonates, it is let settle, and the analysis is completed by filtering as in the former case. —*Bulletin de la Societe Chimique de Paris.*

GERMINATION OF SEEDS.

I have lately read in the *Gardeners' Chronicle* some papers on the germination of seeds; may I be allowed to note my experience in this matter? I do not find Gentiana seeds take long to grow, nor do I find that plants with whorled flowers differ from each others in their period of germination. What I do find is this:—Old seeds take longer to germinate than fresh ones; that soft or rain water is far superior to hard water, indeed hard water always impedes germination, and often stops it altogether; that lime to be beneficial must be in the soil, and not in the water. There are some seeds which, as everybody knows, take longer than others. I find, as a rule, that the seeds whose embryos are more highly developed germinate faster, some even germinate on the mother plant, and the less developed the embryo the longer is the time required to germinate. There are many seeds whose embryos are quite indistinguishable from the albumen, these are the slowest to germinate; witness some Palms, which take so long to grow, whilst others, as Phœnix dactylifera, whose embryo is visible, germinate in a few days. Then there is the case of ripeness. All seeds when fully ripened take longer than when sown when just formed; for example, if you gather Schotia pods when just turning colour the seeds germinate much sooner than when the pod is allowed to turn black or fully matured. But then there are peculiarities; some seeds will germinate with more vigour and make finer plants when allowed to germinate in the fruit. Take, for example, the Orange tribe, whose seeds grow with other facility when allowed to germinate in the rotting pulp. Elais guineensis is another example; these seeds germinate better if allowed to remain in the oily fruit. Other seeds taken from the same receptacle, some will germinate at once, others take months; for example, Poinciana regia, a beautiful African plant—most of the seeds from one pod will germinate in a few days, others take months, even a twelvemonth. Other seeds, sow them how you like, and at whatever time of the year, will all germinate together at their proper season even to a day. There is also a circumstance to be noticed: a pan of seeds will grow at the same time, yet there are one, two, or more seedlings outstripping the others in their development; this is the case with some seed, and I always retain these for seeding from, as they are evidently of stronger constitution. Improper conditions of soil, &c., will also impede germination. I find that when a current of electricity is caused to run through the soil, germination is impeded and not accelerated as I supposed it might be; but if you dip the two ends in an aquarium, the plants seem to find a relish, and show better colour. The rare section of Demersa which throw down a stolon will often remain twelve months before the plumule is developed; this is the case with some plants from the marshes of Mozambique. I have only found this in another seed sent to me from the Brazils without any designation of its habitat.—Chev. D. G. de Nautet Monteiro, Almada, Portugal.—*Gardeners' Chronicle.*

TEA PLANTING IN NATAL.

"Ager sine cultura fructuosus esse non potest."—(Cic.

Kearsney Estate is five miles from Stanger, and the road leading thereto offers pleasant and charming scenery, and the landscapes are beautiful. On reaching the top of the hill overlooking Stanger you are struck by the picturesque panorama you have before you. The several farms in the distance speak highly, by their appearance, of the enterprising and agricultural spirit of their owners. Entering the estate you notice a large area of coffee trees, now abandoned; and on ascending the hill to the house, at the right hand side of the large avenue of magnificent blue gum trees, you come to the tea plantation, which has taken the place of the coffee trees. Acres and acres are covered with this precious tree, amongst which can be noticed by their size trees of all ages. The young plants are very promising indeed, and I have been told by the proprietor of the "Kearsney" Estate—and I was able to see it myself—that the tea plant likes a light or sandy soil, in fact it grows splendidly in such a soil. The old trees, that is to say those of three, four, and five years, are covered with seeds, and some are in full blossom. These are left for seeding, and in consequence are not pruned. In a month there will be a very large amount of good seed ready for sale, not to speak of the young plants that can be applied for. Judging from what has been already pruned, this year's plantation will give a splendid yield. The preparation of the leaf is very simple, and does not require as great an outlay and trouble as the manufacturing of sugar. Four hundred pounds of good, sound, first-class dried tea will soon be ready for the market, and a better quality of tea than the one already obtained can hardly be had in Natal. The tea I have tasted has the same flavour as the one you drink in "Assam," and is far superior in taste to the ones imported in this colony. For cheapness in price it compares favourably with the ones you can get at the various stores. Three pounds of green leaves give one pound of dry tea, and a tea plant of three years' growth gives several pounds of superior dry tea. The plant itself is a charming tree, which planted in a garden will be quite an ornament. It resembles the camellia, and its white flowers are very pretty indeed. From what I have seen and tasted, considering the rapid growth of the plants and the small outlay of capital it requires to grow them, the tea-planting at Kearsney proves a success; and tea-planting is likely very soon to be a source of revenue in Natal, and will be grown with advantage at places where coffee and sugar are no more thought of. It is but right to mention that this result is due in a great measure to the well-known energy, intelligence and ability of the proprietor of Kearsney and to cite the name of James Leigh Hulett, junr., is enough to tell intending visitors of this splendid estate who will be willing to go and convince themselves of the reality and success of tea planting in Natal, not to speak of the pleasant and home-like hospitality they will receive.

Choisy, January 26. "IGNOTUS."

—*Natal Mercury.*

COST OF MANURE.

The cost of fertilising the land is a subject of prime importance in agriculture. Most amateur farmers who come to grief or loose their money—as that class of agriculturists often do—are wrecked on the manure bill. Practical farmers will understand that in speaking of the manure bill I do not refer merely to the direct purchases of manure, but to all charges incident to the fertilisation of the land, including the cost of feeding stuffs consumed by stock, whether the "stuff" be purchased or grown at home. Unpractical farmers who do not keep accounts, and do not really know how the stock-feeding part of their business stands, are apt to imagine that farmyard dung costs them nothing. There is no subject that has been more constantly thrashed by speakers and writers during the past thirty years than high farming. Those who approach the scientific bearings of the subject will learn what our fortunate predecessors, in dearer times for corn, may not have thought of, that, in the present struggle between the farming of England and the virgin soils of America, the system of high farming is handicapped with an adverse scientific principle which has often been entirely ignored. Virgin soils are unhampered, since they yield their whole crop from their own substance; but English soils depend on manure They yield something, no doubt, from their own substance; but, in spite of deep ploughing and steam cultivation and all other expedients, nothing but abundant manuring can secure continued heavy crops. In America the production of corn is a manufacture of the soil's own substance, aided by the atmosphere; in England, under high farming, the soil yields little of its own substance—sometimes it yields nothing, but gains by the process—and its crops are "manufactured" from dung and other manure as their raw material. The advice so often, and sometimes so heedlessly, offered about increasing the amount of farming capital and beating the Americans by doubling our crops, has a sort of patriotic ring about it. High farming was always regarded as a good thing for the country, though no business can really be good for the country unless it be conducted at a profit; and those who read the first report of the Agricultural Commission may remember how many persons were shown to have suffered severely by high farming. A gentleman in Staffordshire, whose farm is his own, so that he enjoys fixity of tenure, lost £2,287, or one-fourth of his captial, in one year; and half the loss was due to the heavy payments for feeding stuffs and manures. A high farmer, who "goes in" for 10 bushels an acre more than his neighbour loses it in a wet season, and his risks are enhanced by the operation of a scientific principle. If the double dressings doubled the crops, the man who applied much manure would only incur the same risk as the man who applied little, and with high farming for a weapon we should easily flog the Americans; but, quoting the words of Sir John B. Lawes, "the higher you farm beyond a certain limit, the less is the amount of increase you obtain for a given amount of manure, and therefore the grater the cost of that increase.

One cannot but conclude that agriculture is confronted with a great difficulty in having to meet lower prices by increasing the crops. In solving the problem how to adjust his buisness to existing circumstances, I cannot think that "low farming" will be resorted to, since land that has been long cultivated yields but little without liberal dressings. The practical farmer will probably ask himself how he can best fill the soil with manure at the least cost and risk, and he will then proceed with the cultivation of the best crops for his neighbourhood. He will not fatten bacon hogs, and if he rears his own bullocks he will not keep them till three or four years old, young beef, as every practical farmer knows, being far more profitable than old; and the same may be said of mutton. The prize farm near Reading, which the writer had the pleasure of visiting, and which has a thoroughly practical tenant in Mr Radcliff, reads us a useful lesson, as, indeed, all well-conducted farms must do in these trying times. We may learn what the ablest farmers and proprietors are doing to meet the times in the extension of pastures and the diminished arer of wheat. It happens that the prize farm is well adapted for wheat, and that the straw is exceptionally valuable in that neighbourhood; but, looking to the cattle for the lesson we require, we find that milk, mutton, and beef—all of the best—and 10-stone porkers are the leading animal products, and the system of feeding and management is so good that I have no doubt the manure is obtained at a reasonable price. The cattle at the prize farm, too, are bred with great skill and care; the forty cows (on a farm of 230 acres) are first-rate milkers, and excellent for beef, as their achievements at the Agricultural Hall at Islington testify.

Our test is "the cost of manure;" and when we consider the need for manure in farming an old country, and that good farming implies a heavy manuring of the first crop, the turnips, of the four-course rotation, with the folding off of a portion of that crop for the barley that follows, and one dressing at least between the clover and the wheat, the third and fourth crops, it is evident that that economical manuring of the land is a subject of the first importance. In Sir James Caird's volume on "English Agriculture" republished from the *Times*, he

referred to a "cause of much national loss to agriculture," existing in the "immense mass of fertilising matter which runs to waste from all the large towns of the kingdom." It is useless enlarging on this loss here, intimately connected though it be with the cost of manuring the land, and I will, therefore, only add that the best remedy for the waste lies in the economical manufacture of farmyard dung by skilful stock farming, and in the continued supply of "artificial manures" at a moderate price.—T QUICKLY.—*Field.*

CULTIVATION OF FLAX IN NEW ZEALAND.

Consul Griffin states that *Phormium tenax* is by far the most valuable fibrous plant indigenous to New Zealand, and since 1809, it has been an article of export. The attention of Europeans was first directed to it by Captain Cook, who described it as something superior to either flax or hemp. The Maories have for many years used it for binding together the frame-work of their houses, and for making clothing, baskets, fine mats, fishing nets and lines, and sails for their boats and canoes. *Phormium tenax* is sometimes called the flax lily. The leaf varies in size from three to fourteen feet in length, and from half-an-inch to five inches in breadth at the widest part. It grows in bunches or groups of plants, each shoot has five leaves, and, on an average, about ten of these shoots form a bunch. The leaves are perennial, hard and sword-shaped, with a stalk rising five or six feet above them, bearing a profusion of yellow, and sometimes red flowers, followed by triangular pods filled with flat and thin black shining seed. The plant attains its full growth in three years, when the leaves generally split at the end, and it first comes into flower. It is said that in rich soil the flower rises to a height of twenty feet. The leaves are smaller than those of European flax and hemp plants, being composed of cellular trusses running the whole length of the leaf incased in a green substance. The trusses consist of two parts wood and bast, the latter forming the fibre so highly prized. The vascular bundles compose the inner bark of the plant, and serve to circulate the juices which are taken from the soil by the roots; these consist of exceedingly fine threads, one over-lapping the other in such a manner as to give a free circulation throughout the leaf. The plant is indigenous to New Zealand and Norfolk Island, although it has been transplanted in India and other countries. It grows best in rich, moist, and well-drained grounds, and attains its maximum growth on the banks of running streams. When the leaves are full grown the natives gather them when green, and separate the fibres; they scrape the leaves with a shell, and then divide them with a comb. They are then put in the sun to dry, and when dry are perfectly white, soft and silky to the touch. It takes only a very short time to prepare the fibre, and about one ton of fibre is produced by the natives out of four and a half tons of green leaves. A full-grown plant will produce on an average about thirty-six leaves, besides shoots from the roots, and it takes about six leaves to yield one ounce of fibre. At this estimate an acre of ground planted three feet apart would yield about sixteen hundredweight of fibre. There are very many varieties of the *Phormium tenax*, among them being the *aonga*, a variegated flax; *atewhiki*, a very white fibre, used for making fine mats and garments, the leaf is narrow with a reddish tinge and bright scarlet lines; *sapoto*, cultivated at Coromandel, Kawhia, and Waikata, glossy leaves rather red at the edge, having a general orange green appearance; *savariki*, a species of very fine and soft texture used for making ornamental mats, the leaves tapering, of a dull olive green. There are several flax mills in New Zealand, principally in Auckland, used chiefly for dressing the flax for rope making. Here the green leaves are stripped by revolving rollers with projecting beaters travelling at a high rate of speed, these crush the epidermis against a fixed plate so arranged as to allow room for the fibre to remain intact. The fibre thus freed from the leaf of the plant is washed by various methods, put on the ground or on lines to dry and bleach, finished by an arm or barrel scutch, and when boiled is ready for market. All the machines used are identical in principle, and vary only in the details by which the principle is carried out. This principle is that the leaf is held between horizontal feed rollers, revolving at a certain speed, while as the leaf passes out from them, a drum, armed in its circumference with iron beaters, and revolving more rapidly than the feed rollers, strips the epidermis and tissues away from the fibre, means being provided for adjusting the beating drum to a proper distance from the roller or bar against which the phormium leaf is stripped, so that the leaf may neither, on the one hand, pass through without being crushed, nor, on the other, have the fibres cut. The method of preparing fibre by machinery is a great improvement over that pursued by the Maoris, as regards the quantity produced, as they do not obtain from each leaf one-fourth of the quantity which is obtained in machine dressing. The natives cut off the leaves about six inches below the point where the two blades adhere together, and reject the coloured edges; they also take much time and pains in preparing the leaf, often soaking it for four or five days in running water, and then beat it with a stone or mallet. This process is repeated over and over again for four or five weeks. Consul Griffin states, however, that the fibre dressed by the natives is far more valuable and beautiful than that prepared by machinery. The principal competing fibre with *Phormium tenax* is Manilla hemp. This is made from a species of plantain, called *Musa textilis*, which is planted generally on the slopes of hills, and requires shade and plenty of moisture. The trees are planted about eight feet apart, and are cut down at the end of the third year, and made into fibre. A full-grown tree is estimated to yield about one pound and a-half of hemp. The process of manufacture is as follows:—The tree is cut down and stripped of its linings; these are then cut into pieces three or four inches wide, after which they are drawn underneath an instrument resembling a saw fixed in a block of wood. The fleshy part of the cortex is scraped off, and the fibre alone remains, which is then placed in the sun to dry. Two persons, one engaged in cutting down the trees and stripping them, and the other in extracting the fibre, can work up about 25 pounds of hemp in one day. The value of *Phormium tenax* exported from New Zealand, in the year 1880, amounted to £16,267.—*Journal of the Society of Arts.*

FARMING IN JAPAN.

GRAIN—TEA—SILK—AND SUGAR.

Consul Van Buren, in a report upon the laws, religion, government, &c., of Japan, has given some details respecting the condition of the agricultural classes in that country. He states that the Japanese farmer, under the old system of classes, ranked next to the "Samurai," or governing class; in the new order, he holds the same position in public opinion and general estimation. He is now owner of the soil he tills, and is taxed according to its producing capacity. The "Kocho," or village officer in all agricultural villages, has always been a leading farmer, and some villages had and still have the right to choose this officer. His duties were to settle petty disputes, maintain the peace, keep a register of the inhabitants, grant travelling permits, arrest thieves, and to be a general adviser for the whole village. Within the last two years the position and influence of the landholder has been greatly enhanced, a decree having been promulgated, by which local election assemblies have been created, the electors to which are confined to those landholders who pay at least a land tax of 40s. Farmers in Japan have no seasons of rest, as in colder climates, for the climate in nearly all parts of the country is so mild in winter as to admit of raising the hardier crops. A considerable percentage of the landowners are not workers, large numbers of the tea, silk, rice, tobacco, and sugar producers being able to employ labourers. Almost every farmer can read, write, and keep his farm accounts. He sends his sons to school, and his daughters are taught music and needlework at home. All labour on a farm is mere hand-work, a plough being seldom seen. Sometimes, in the lowland rice-fields, an implement, five feet in length, with a wooden cross-piece, and depending iron teeth, twenty inches in length, set four or five inches apart, is used, with a horse, as a pulveriser of the soil, after the latter has been thoroughly dug up and worked over with a mattock. Ninety-nine per cent, however, of all labour is still manual. In 1878, the number of farmers,

out of a population of 35,000,000, was something over 15,500,000, of which over 7,000,000 were women. The wages of an able-bodied farm-hand are about £7 per annum, with board, and £10 without board, female labour being much cheaper. To perform work in a house, or on a farm, stout healthy women are engaged at from 35s. to 40s. a year, with food, and from £5 to £6 without food. The number of hours of labour will not average more than nine, and in many cases does not exeeed eight. The Japanese farmer is an easy taskmaster, and treats his farm labourers with great kindness. In ordinary farming there is little skilled labour, but in tea, silk, and sugar cultivation and preparation skill and experience are required, and paid for with higher wages. A good tea-firer on a tea plantation, or a silk winder, receives double the wages of the unskilled labourer. The food of a farm labourer is almost entirely vegetable, and consists of rice, barley or wheat, millet, beans, pease, turnips, potatoes, onions, carrots, and a few other vegetable products. In some districts rice is too high in price, and only barley, turnips, and millet are used. Religion, custom, popular prejudice, and force forbid the use of animal food. The clothing of the farm labourer in summer is little more than a thin covering for the body, in winter an addition is made of one or two cotton garments, with straw sandals or wooden clogs. The entire clothing for the year does not cost more than 16s. or 17s. Several holidays are allowed each year, such as religious festivals and family celebrations. When a man and his wife work for yearly wages they will receive, without board, about £15. From this they have to pay from 30s. 40s. for a small-roomed house, consisting of two or three rooms, and buy clothing for a family of four or five. A small garden is generally attached to the house, from which one-half of the living is produced, and it is no uncommon sight to see a child of six or seven years, with a baby of six months strapped on its back, gathering brush or dried grass on the commons for fuel. The homes of the rice, silk, and tea farmers are the best of all the agricultural labourers in Japan. The house is often as large as thirty or forty feet square, always one storey high, with a thatched roof, strongly built, with verandah in front, and consisting of five or six rooms, one being generally kept as a spare or reception-room. On the tea plantations, ordinary labour wages are paid for the tillage of the soil, but the man who trims the plant must be a skilled labourer, and receives as much as 1s. 6d. a day. The tea picking is done by women and girls, and requires great care. When working by the day, they are paid from 5d. to 6d. Tea rollers and firers must be skilled, and can command from 7d. to 10d a day. Silk production also gives very considerable employment to farm labourers, and as better processes of preparing silk are continually being introduced, and, consequently, a better article is produced, there is a greater demand for skilled labour, and increased wages are offered. Mulberry plantations are found in fifty of the sixty-six provinces of Japan, and the business of silk production is carried on in the house where the farmer resides. The mulberry leaves are either picked off by women and children and carried into the house, or the young branches, with the leaves on, are cut off and taken there, where the leaves are picked off, washed, cut up, and given to the worms. When the cocoons are ready for winding, that is also done by women and girls. To make an even thread requires experience, care, and skill, and such labour commands wages accordingly. Spinning, warping, dyeing, and weaving are all, more or less, skilled branches, and require skilled labour. The man who tends the trees commands ordinary farm wages, while the leaf pickers, winders, spinners, and weavers of plain cloth will get as much as 10d. to 1s. 8d. a day. Weavers of fancy-patterned goods are paid at a much higher rate, receiving as much as 4s., but this is very exceptional. On the cotton plantations the labour employed is not skilled, and is paid for at a very low rate. It was estimated, in 1875, that the total extent of land in Japan under cultivation was about 12,000,000 acres, giving to the actual farming population three-quarters of an acre per head. The tillage is of the most thorough order. Two crops are invariably raised each year, so that the producing capacity of the area cultivated is double that of the number of acres named.—*Journal of the Society of Arts.*

PROPAGATION BY BUDDING.

As a school-master is obliged to begin each year with a primary class, so in a journal like ours, it is necessary to now and then repeat certain rudimentary lessons. There are many—probably the majority—of our readers who look to the *American Agriculturist* as the sole source of their information

Fig. 1.—A BUDDING KNIFE.

in all that relates to agriculture and horticulture. When these ask us to tell them how to layer plants, how to prune, how to graft and to bud, and to do other operations, they will not be satisfied if we refer them to certain books for their information.

GRAFTING AND BUDDING

have the same end in view, and the operations are essentially the same, but differ greatly both in the manner and the time of performing them. In both, budding and grafting, we place a variety that we know and wish to increase, upon a tree of the variety of which we know nothing. It is a well known fact that our esteemed varieties of fruit are in an unnatural condition; so that when we plant the seeds of these, there is no certainty that the trees thus produced will bear fruit like the parent tree—that from which the seed was taken. The seedlings of our cultivated fruits may produce better kinds than those from which the seed was taken, but generally the fruit will be poorer, and there is no certainty about it. It is on account of this uncertainty that we propagate the varieties that we know, by grafting or budding them upon seedlings about which we know nothing. In grafting, we use a scion, a twig upon which are *several buds*, of a known variety, and insert it upon a tree raised from seed. We plant this scion, or cutting, not in the soil, where it may take root, but upon a tree which already has roots. In budding, we plant a *single bud* upon another tree. The operation of

BUDDING IS SOMETIMES CALLED INOCULATING,

and the use of this term, "inoculating," has given rise to an incorrect popular notion. In the inoculating of animals, including the human subject, we introduce a virus, or disease, which affects the whole system, and causes certain changes to take place within it. Many have an idea that in "inoculating" a plant, a similar influence is exerted, and that the nature of the plant is somehow so changed by the operation, that it will afterwards bear good fruit. This view of "inoculation," or budding, is entirely erroneous. Had the bud been left on the tree which bore it, it would have expanded, and pushed from it a green shoot, which in time would ripen and become a branch, and ultimately bear fruit. When we remove the bud from its tree, and plant it in another tree, it expands, a shoot appears; this grows and branches, and the bud, in time, becomes the tree, as all the rest of the tree in which it was planted is cut away. In budding, we need

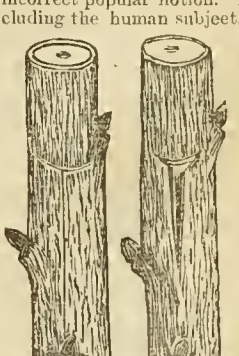

Fig. 2. Fig. 3.

THE STOCK AND THE BUDS.

The stock, or plant in which we insert the bud, is a young tree of the same kind as the bud, or of a nearly related kind. Peach, Plum, and many other stocks are young trees raised from seeds; other stocks, as the Quince for budding the Pear, and those for the Dwarf or Paradise Apple, are young trees produced by layering. In budding the Peach, the stocks are from seeds planted the spring of the same year; the plants, with good cultivation, will be large enough to bud in August or September. Apple stocks and others grow for two or more years. But we must now assume that one has his stocks ready; the next step is

THE SELECTION OF THE BUDS.

It is all important that the buds be true to name; hence they should be taken from bearing trees. When a fruit tree has completed its growth for the season, that is, when the branches have ceased to increase in length, there then appears in the *axil* of each leaf—the angle where the leaf joins the stem—a bud. Examine any shoot of the current season's growth, and these buds will be found; those near the end of the shoot will be immature, those at its base small and poorly developed, while between these extremes will be several well-formed, plump buds. In securing the buds, take always the shoots that have grown this year. Such sticks of buds may be cut, and if prevented from drying, may be kept in good condition for a week or ten days. When the shoots are cut, the leaves should at once be removed by cutting through the petiole, or leaf-stalk, half of which should remain attached to the shoot. Such sticks of buds may be kept in damp moss, damp sawdust, or be wrapped in wet cloths. If simply moistened and inclosed in a tight tin box, they will keep well.

THE TIME FOR BUDDING.

varies with the kind of fruit, the locality, and the season. The usual succession is Plum, Pear on Pear stocks, Apple, Cherry, Pear on Quince, and Peach. The precise time for each kind is, when the bark on the stock will "run,"—that is, when it will readily part from the wood, this being the condition necessary in the stock; of course the buds must be plump and well formed.

THE OPERATION OF BUDDING.

is a very simple one, and those who make a business of it become very rapid budders. In the largest nursery in the Southern States, the best

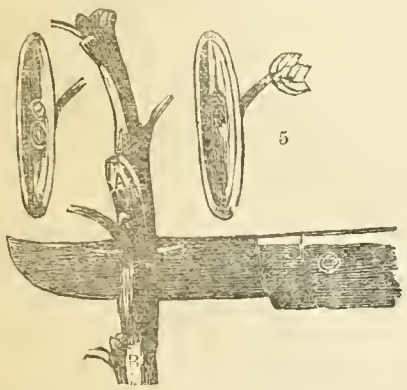

Fig. 4. Fig. 5.

budder is one who was formerly a slave. In the large Peach nurseries, the budder has two assistants; one goes ahead and prepares the stocks, by rubbing or cutting off twigs, and removing leaves from the place where the bud is to go; the other follows and ties the buds. Of course the amateur who inserts but a few buds, will perform all these operations for himself. It is a matter of importance to put the bud on the right side of the stock. If the rows run east and west, the bud is inserted on the north side, and when they run north and south, on the west side. It is also important to insert the bud as low down on the stock as a proper place can be found for it.

THE BUDDING-KNIFE.

is the only implement used in budding, and every budder has his own notions as to the proper form of the blade. Budding-knives, like that in fig. 1, are made with a thin ivory point at the end, for the purpose of lifting the bark, but experienced budders use the blade for both making the cuts and lifting the bark. The first step is, to select the place for the insertion of the bud. Two cuts are made upon the stock, down through the bark to the wood; one crosswise, and the other extending from this downwards, forming a T-like incision, as in fig. 2. Figure 3 shows the corners of the bark lifted, ready for the bud. The bud is now to be separated from the stick, though some budders first cut the bud, and hold it between the lips until they have made the cuts upon the stock. Figure 4 shows the manner of removing the bud from the stick; the knife enters at *A* half an inch above the bud, and by a downward cut, comes out at *B* three-quarters of an inch below it. In making this

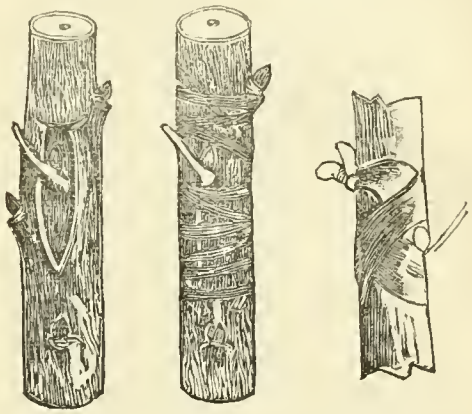

Fig. 6. Fig. 7. Fig. 8.

cut to remove the bud, as little wood as possible is to taken off with it. When the bud is removed, it will consist of, besides the bud itself, a shield of bark, a portion of petiole or leaf-stalk that has been left attached, and a small portion of wood removed in the cutting, as in fig. 5. European budders direct the removal of the attached piece of wood, but our budders pay little attention to it, as unless it parts very readily from the shield of bark, the base of the bud may be injured by its removal. Holding the shield of bark and its bud by the leaf-stalk as a handle, it is placed in the incision (fig. 3), and pushed well down. If the stock is in the right condition for budding, the pushing of the bud to its place will be easily done, and the bark upon the stock need only to be lifted at the corners of the cut, to allow of the entrance of the shield; the bark at the upper end of the shield is then cut square across, so that it may fit the horizontal cut on the stock. Figure 6 shows the bud in place, and ready to be tied. The tying material is usually bass-bark, moistened to make it flexible; woollen and cotton yarn are both used, and some budders use thin and flexible corn-husks, selected from the interior layers at husking time. Figure 7 shows one method of tying buds, and fig. 8 another. In all cases, the object is to hold the parts in closest possible contact, and yet not injure the bud. In about 10 days, or two weeks, after the insertion, the buds must be looked to; the stock is still growing, and a serious strangulation may occur if the ties are left as they were applied. At this time it may be ascertained if the operation has been successful, or if the bud has "taken." If the bud and its bark look shrivelled, and the attached leaf-stalk is still remaining and dead, the operation has failed. If, however, the bud is still plump, the shield of bark bright, and the bit of leaf-stalk has dropped, the operation is successful. In case of failure, and the stock is still in good condition, another bud may be inserted; otherwise the stock may be left until next spring, and then be grafted. When the buds are found to be all right, the tie may be loosened, or cut through, to allow of the growth of the stock. The inexperienced will do better to loosen the knot sufficiently to allow of the increase in diameter of the stock, but retain the tie to protect the bud until later. When a bud has taken, and the ties loosened, nothing more is to be done until the following spring, when all of the stock above the bud is to be cut away. It is, of course, important to properly label the budded trees, that the kind of bud inserted may be known. In nurseries, this is done by labelling the rows, but in small operations, the stocks may each be marked by a label with the variety of bud inserted. —*American Agriculturist.*

TEA CULTURE:—A REVIEW.

(From the North China Herald.)

The *Tea Cyclopedia*; a Volume of Selections from Leading and Original Articles, Correspondence and Papers regarding matters of permanent interest and value concerning Tea and Tea-science, Tea-blights, Soils and Manures, Tea-cultivation, Buildings and Manufacture, Miscellaneous Tea-topics, Tea-statistics, etc., etc., etc. Calcutta—office of the *Indian Tea Gazette*, 10 Hare St.

Though we live in the land of the tea-plant, it is astonishing how little the average resident in China knows about it. Even those whose livelihood depends upon the once "noble article" are often found to be as ignorant as is any outsider: their knowledge is confined to the assumed value of the leaf on the London or New York markets, and they take little or no interest in the details of its production and preparation for sale. So great was the want of knowledge displayed by those who would naturally be expected to be the best informed upon the subject, that until quite recently, and owing solely to the investigations made in India, it was an axiom of general belief that black and green teas were gathered from totally distinct plants. Such enquiries as might have led to more accurate information were beyond the scope of the merchant dealing in the article, and the best tea-taster was often he who, confining himself to a practical knowledge of its market value, had the least theoretical acquaintance with the conditions ruling its production. And the apathy thus displayed is not confined to the foreign merchant. The Chinese themselves with whom he comes in contact, brokers and hongmen, appear equally ignorant, and little information is to be gleaned from them. Unless the Western buyer is prepared to speak the language and to spend a good portion of the season in the interior, watching with his own eyes each stage of production, the result of his stay in the country will be no greater, as far as a real acquaintance with his subject is concerned, than if he had never wandered a hundred miles from the dingy purlieus of Mincing Lane.

While thus, in old times the European tea-merchant in China was content to purchase at the sea-port and ship home whatever the native teamen produced for sale, satisfied to reap an easy profit without asking troublesome questions; in the present epoch profits are no longer easy; the bright prospects of former decades are clouded over, and the newspapers, when they allude to the subject, are filled with wailing and lamentation over the hard times on which we have now fallen. Barely twenty years ago a cloud no bigger than a man's hand appeared upon the Western horizon in the shape of an export from Calcutta of about one million pounds of Assam tea. None looked upon this indication as a warning of a coming storm, for it was said Indian tea is bitter and unpalatable, and is a novel experiment not likely to succeed on a large scale or to oust from its supremacy the delicate fragrant growth to which long custom has wedded tea-drinkers all the world over. Yet the small cloud has increased fifty-fold, and the storm has begun to break with no little violence, until we find the consumption of China tea actually receding and the average value reduced nearly one-half. The time has now come when all concerned are compelled, willingly or not, to pay some attention to the rationel of the subject, and endeavour to enable themselves to form a judgment regarding both the present position and the future prospects of the trade in which they are engaged.

A most serviceable aid to such an inquiry is the file of the *Indian Tea Gazette*, which in our opinion every person interested in the cultivation or the sale of the article should read:—if not in the numbers of the journal as they appear monthly in Calcutta, then in the condensed form as given in the work under review, in which is accumulated the cream of eight years' issues. This work possesses farther the advantage of having its contents classified according to subjects. Unlike Colonel Money's well-known standard work on tea-cultivation, the *Indian Tea Gazette* is an accumulation of facts bearing on every branch of the subject, contributed by various authors, all specialists, and thus exhibiting the matter from every possible point of view. Controversies are carried on by various correspondents, and the reader is enabled to draw his own conclusions. Every fresh discovery or suggestion as to the improvement of the manufacture or in the methods of carrying on the trade are freely given to the public, thus setting an example of cordial interhelp which the merchants in China would do well to emulate instead of as at present (as it would seem from such glimpses of the buying in Hankow as are from time to time vouchsafed to the general public) throwing dust in each other's eyes. In India it would appear that any specially fortunate planter hastens to publish the secrets of his success. Thus we have here collated the experience of planters scattered over all the various tea growing districts of India from Chittagong to the Punjaub, and the advantages of different methods argued out, until little doubt as to the best course to pursue in any given case is left. The soil to be chosen, the manuring, the plucking of the flushes, whether at long or short intervals, the withering, firing, packing, shipments, and sale, are all related in detail, and lastly the opening up of new markets and the supplanting of China tea wherever practicable is strenuously advocated and the means of success pointed out. The generality of the contributors are curt and to the point as becomes practical men, but a few wild notions seem still to prevail where China tea is the subject of discussion. Thus at page 23 we find it stated "that the time is probably not far distant when the tea trade will buy entirely by analysis, supplemented in a few cases by a taster's report. An experienced palate will detect particular flavours which analysis will fail to show; but a fairly complete chemical examination of tea is of the highest value, whether as a guide to the purchaser, or merely to shew its freedom from adulteration." As well might we resort to chemical analysis to enable us to gauge the bouquet of Burgundy and hence its value. At the same time the long list of methods for discovering adulteration are useful, and the scientific account of the growth and development of the plant interesting in the extreme to the tea-drinker as well as to the grower or dealer; but the fact that the flavouring substances of tea and coffee are chemically identical shews the futility of trying to arrive by chemical analysis at the value of an article grown to please the palate. From an analysis given on page 346 we find that in dried tea the element theine comprises about one-tenth of the weight of the whole. The analyst also states that theine does not produce wakefulness, but that its effect on the system is a sedative one. Theine and quinine are similar in their chemical constituents, and although tea may not cure fever and ague, it doubtless acts as a preventative. The next elements of importance in tea are the volatile oil and the tannic acids. This former element upon which the commercial value mainly depends, and whose quality can only be gauged by the palate of an expert, forms in the best teas only a fiftieth part of the weight of the whole. To this is due the distinctive flavour, and no chemical analysis of it has yet been made. It is to the presence of this oil that the wakefulness attributed to tea drinking is due, and it is stated by those who have made these subjects a special study that it acts upon the system in the same manner that *digitalis*—the foxglove—does.

It is a well-known fact that this sleepnessness and, when tea is taken to excess, palpitation of the heart is more marked in green tea then in black tea-drinkers. This latter *kung-fu* or "worked" tea as it is technically described, and *hung-cha* or "red" tea as it is popularly known by the Chinese) loses a portion of its volatile oil in the "withering" (or, as it is improperly called "fermentation")* which is replaced by an empyreumatic oil developed in the subsequent firing and to which the peculiar soft flavour of Congou is due. A similar effect is produced in the curing of tobacco; upon the effectual manner in which this is carried out depends the absence of the biting acrid taste of ill-cured leaf, and its consequent nauseating effects even upon the system of the practised smoker. The volatile oil is still there, but its character is changed. Hence the importance, in obtaining a well-flavoured cup of tea, of employing soft water capable of dissolving the volatile oil, not steeping it too long so as to overpower the flavour with the bitter extract of tannin, nor of boiling the tea, by which the volatile oil is driven off and lost.

* The reviewer has here fallen into a curious mistake. The process of withering, which makes the gathered leaves flaccid as finest satin, precedes the rolling process, after which comes fermentation.—ED.

Tannic acid or tannin forms nearly one-fourth part of the chemical properties of tea. It is a powerful astringent, and is remarkable as being entirely absent in coffee. Some attribute to this element the dyspepsia from which ardent tea-drinkers suffer; others believe that it aids digestion, but its true physiological action is still a matter of doubt.

The above is a specimen of the exhaustive information to be culled from the book before us. Part II. is devoted to a description, illustrated with handsome plates, of the insect enemies of the tea plant and the best methods of their destruction. These are "rust, mosquito-blight, the tea-grub and the red spider." We have never heard of the plantations in this country being ravaged by these pests, whom doubtless some people engaged in the trade would not be sorry to see introduced for a season into China.* They never fail to have a material influence on the production in India, and without them our rival would be still more fatal. The details of their ravages and the different methods of combating them are highly interesting, as are the chapter on choice of ground for tea cultivation, and the various processes of planting, curing and packing adopted in different gardens. We almost think an opening for an enterprising "tea-man" presents itself in India to introduce the Chinese system of bulking, which appears to be entirely unknown there, and which necessitates the bulking in the London warehouses of all Indian tea. This process, pursued at the termination of the voyage, is doubtless the cause of the bad keeping qualities of Assam tea. The tea is, as is well known, after being for some time exposed to the London air, replaced in the chests, the lead lining of which has been partially destroyed, and which it is never attempted to re-solder. In China, the leaf from many gardens is brought up in small quantities and in its natural state by the so-called teamen, who erect or hire packing houses in the centre of a district, and then bulk their purchases into chops of 500 to 2,000 chests before packing. Thus a wonderfully homogenous tea in merchantable quantity is placed upon the market, and, until it reaches the consumer, but a small proportion of its bulk needs subsequently to be exposed to the atmosphere for the purposes of sampling and taring. Whether a similar undertaking in India would afford a safe investment of capital remains to be proved by experience; but we cannot but think that such a division of labour would prove acceptable at least to the smaller planter, who would thus be enabled to realise his crop immediately on the spot and be absolved from the risk attending the subsequent stages of manufacture and sale.

Another chapter is devoted to Brick tea, in which our Indian neighbours are ambitious of emulating Hankow in the commerce with Thibet.

The question of labour, long tables of satistics, the relations of planters to the government, the various items that go to swell the cost of production, are all fully treated of. For the purposes of comparison it would be most interesting to be placed in possession of similar statistics of the China growth. These are unfortunately unobtainable in the present condition of the country, but the time will doubtless come when the foreign advisers of the government will shew them the necessity of doing all in their power to facilitate the obtaining of information and to improve the methods of culture.

The competition of India is becoming more serious each year, and, handicapped as China tea is by greater distance and by an export duty of fifteen to twenty per cent *ad valorem*, it seems to be only a question of time when it must succumb to its more favoured rival. Science against hand-to-mouth methods must prevail in the end, and with, in India, such ardent intelligence and progressive knowledge devoted to the subject, as illustrated in the work before us, China, so long as no need of improvement is felt, must ultimately take second place. As long as European merchants continue to buy freely all that the Chinese produce, this need will not be felt; but the signs of the times point to the coming exercise of a compulsory reticence on their part, totally alien to the ancient and still prevailing traditions of the trade. Hard facts will have to be faced and their logic may produce a change which the most lucid reasoning has hitherto been powerless to effect.

A few defects it is our duty to point out ere we quit what has been a most interesting study. Some incorrect statements among so large a number of contributors are almost sure to creep in, and notably in regard to China, with the tea-industry of which the writers have probably no practical acquaintance. Here we find such glaring misstatements as these.—"China never sends us her best teas"—"China, whose people began making tea two thousand years ago" (p. 293) whereas a few hundred years would be nearer the mark:—"The Chinese destroy the gum by overfermentation" (p. 296). Then we find the idea prevailing among several correspondents that "China tea is more or less adulterated," the fact being that with the exception of a very few low-class teas prepared in Canton, adulteration is practically unknown, there being more genuine tea than the packers in the country can absorb.* There is practically no limit to the quantity of tea producible in China, the portion, large as it is, packed for foreign consumption, forming probably but a small proportion of the total yield.

The *history* of tea cultivation in India forms another most interesting chapter. We learn that the cultivation was originally introduced into Kumaon under government auspices in the year 1835, when two small experimental gardens of three and four acres each were planted with seed sent from China by Mr. Gordon. This was the result of a Committee appointed by Lord William Bentinck on the 24th January, 1834, "for the purpose *** of the introduction of the culture in India and the superintendence of its execution." These early plantations appear to have languished under official superintendence until the year 1843, when Dr. William Jamieson paid his first visit to the Dehra Dun; and in September of that year a favourable report was given on the first sample of Indian tea ever seen in England by the celebrated firm of W. J. and H. Thompson in Mincing Lane. Dr. Jamieson had shewn that its culture could be made a commercial success, when in 1850 Robert Fortune was despatched to China to obtain both seeds and workmen.

We will conclude our too lengthy notice with a few figures extracted from the tables which extend to the year 1879. In that year the total area of land under tea cultivation was 200,000 acres, producing an average yield of 216 lb. to the acre, making a total production of 44,700,000 lb., employing an army of 1,200 Europeans and 300,000 natives, and an expenditure of 250 lacs of rupees. It was then calculated that "when all the tea *now planted out* shall have come into bearing, India will produce 70,000,000 lb. of tea!" The land available for the production of the future is practically unlimited.

A. J. L.

COCOA AND ITS CULTIVATION

Considering the large and increasing consumption of cocoa and chocolate, not only in this country but also over a large extent of continental Europe, it is not surprising that some interest has of late arisen amongst those interested in the supply to consider from whence our future consignments are to come. It is to be hoped that nothing will occur either by disease or otherwise to diminish the cocoa crops in the countries that have been so long famed for the cultivation of this valuable tree; it is, nevetheless, the duty of planters for the benefit of the world at large, as well as for their own pecuniary advantage, to introduce and cultivate in their own plantations economic plants of widely different character, and the cocoa is one that should command a large share of attention in countries where the conditions of soil and climate are similar to those of the West Indies or South America, and particularly of those districts which are celebrated for the high quality of the produce. Since the successful introduction of the cinchona plants into India from their native haunts, in the dense damp forests of South America, our eastern empire has been looked upon as the probable future home of numerous

* It is probable they are present, although scarce in proportion to the scattered patches of cultivation. Is there no description of the tea plant and its culture in Chinese, in which insect or fungoid pests are mentioned?—ED.

* Much of the lower qualities, if not adulterated are very poor rubbish. Considering that tea sent from China pays an export duty of 3½d, how is it possible that 6d. per lb. or less in England and Australia can pay?—ED.

other useful plants. Ipecacuanha followed cinchona, but up to the present time its success is far from being ensured.

In the Island of Ceylon, where the coffee plantations have been so devastated by the attacks of the *Hemileia vastatrix*, it is satisfactory to know that the cocoa (*Theobroma Cacao*), has been successful, and quite recently some of the best varieties of cocoa plants have been transferred to Singapore and Fiji. On this subject we quote the following from the Kew Report for 1880—

"Mr. Horne, the director of the Mauritius Botanic Garden, having visited Fiji, at the instance of the governor, Sir A. H. Gordon, reported to the Colonial Office that it was peculiarly desirable to introduce into the islands, as well as the eastern colonies, 'the twelve or thirteen superior varieties of the cocoa plant in cultivation in Trinidad.' Arrangements were accordingly made, and in the course of last autumn (1880), seven Wardian cases of cocoa plants were received from Trinidad at Kew in excellent order, and after examination and repacking transmitted to Ceylon, whence it was arranged that portions of the collection should be sent to Singapore and Fiji respectively. The transmission to Ceylon was fairly successful, and Dr. Trimen has since made the distribution. Individual planters in the East have already largely supplied themselves with cocoa seed from Trinidad. It was thought that it would be advantageous, however, to have in the Botanic Gardens of the colonies above mentioned standard collections of varieties for future observation and experiment. In an official report on the subject, Mr. Prestoe, the government botanist at Trinidad, remarks:—"The best kinds are by no means well known. Indeed, with the majority of growers here they are not known at all, and they never notice a difference in the character of the trees, nor that of the sample of produce, except in respect of the Calabacillo, or wild cocoa, and this they very rarely eliminate. In the whole range of varieties, however, there is a difference in the value yield of at least one to five. Under these circumstances, the value of the cocoa plants now forwarded should be regarded as of rather a botanical or scientific nature than as an agricultural or economic one for immediate effect, for the varieties being separated and described as far as it is practical to have them, there is a base for experiments and tests as to what are their real characters, and what may be done with them in the way of improvement." As usually seen, the cocoa tree averages 14 to 18 feet in height, but if allowed to grow without restraint would attain to 30 feet or more. The leaves are very large, sometimes 7 inches in length.* The plant flourishes best at an elevation of not less than 500 feet above the sea. Notwithstanding that it delights in great heat, it comes to the greatest perfection in sheltered situations. In an exhaustive paper on cocoa cultivation read before the Society of Arts some years since, it is stated that the cultivation of the plant extends more or less in Mexico, Honduras, Guatemala, Nicaragua, and throughout almost the whole of Central America, Brazil, Peru, Ecuador, New Grenada, Venezuela, Surinam, Demerara, Essequibo, and the West Indian islands; it has also been grown in Africa, Mauritius, Madagascar, Bourbon, East Indies, Australia, and the Philippine Islands. Trinidad and Grenada are the sources of the chief supplies, and they perhaps afford upon their western shores the finest possible sites of cocoa plantations. The latter country is of a particularly mountainous character, the mountains attaining even an elevation of 3,000 feet, forming many fertile valleys and fine rivulets, more numerous perhaps than in any other island of equal extent, in consequence of which it is well suited for cocoa cultivation. Considering the fine qualities of cocoa produced in Grenada, that country may be looked upon as the type or copy for planters and cultivators in other parts of the world, and the following notes refer more particularly to the system of cultivation as carried on in Grenada. Upon ground of a steep, hilly character, such as is found in that country, the site recommended should have a west or south-westerly aspect. The crop is said to be more regular, and the outturn more abundant in plantations where there are hills and valleys rather than upon a level. In consequence of the tenderness of the flowers of the cocoa-tree, it is best to select a site for a new plantation not too fully exposed to the effects of high winds, for, from this cause alone, cocoa crops are often defective. The question of shade for trees is also a very important one in the proper management of a cocoa plantation, especially on level situations. On this head we are told: "An alluvial plain, where obtainable with the necessary qualifications and in the proper situation, grows a fine quality of cocoa, but does not necessarily yield the best return. When planted on such a site the cocoa requires to be interspersed with tall trees to obtain the necessary coolness, moisture, and protection from the winds. The *Erythrina umbrosa or Corallodendron*, called in the country "Bois immortal," is much planted in Trinidad, but it must be said of the system that the trees keep out light and air, which are great necessaries. Much moisture is necessary to the perfection of the cocoa, and where near a running stream of water it grows most luxuriantly, but near a stagnant pond withers and dies; while in the former case the water furnishes a supply of moisture to the roots, which seems to act beneficially; in the latter it chills the roots and destroys the tree. The leaves of the cocoa-tree absorb a large quantity of moisture, and it is necessary for the nurture of the tree that the atmosphere generally should have a tendency to decided humiditry."

Regarding soil, a very important consideration in a cocoa plantation, it is necessary that it should be deep and porous, the best is a loamy virgin forest soil where there is a good deal of vegetable mould. Cocoa, however, will thrive in a stony soil because the roots cling to the stones, from which it is said they derive a coolness* and a certain amount of moisture, while they sometimes help to break up the density of the soil. A retentive or swampy soil should in all cases be avoided.

It is necessary before planting commences that the ground should be thoroughly cleared of weeds. In consequence of the tenderness of the cocoa plants when young care should be taken that they are not exposed to a blazing sun or any undue coldness of night air. To protect them from these effects many kinds of trees are used whose broad foliage form a shelter, and at the same time prevent the growth of weeds. Amongst the trees best suited for this purpose are the Plantain and Banana, the fruits of which give a return during the three years that the cocoa plants are coming into bearing. Besides the Plantain and Banana some of the tuber yielding plants are sometimes planted, such as the Manihot or Cassava *(Manihot utilissima)*, Yams *(Dioscorea spp.)*, &c. From April to June is the time best suited for planting the cocoa, though, with proper care, the planting may go on throughout the year. The distance at which the plants should be separated varies according to the quality of the soil, the most satisfactory distance seems to be 10 feet asunder for a poor soil, 15 feet for good land and on rich virgin soils as much as seventeen or eighteen feet, taken throughout in Grenada, if planted about twelve feet apart, it is about the best average distance. The system adopted by the natives in Grenada of close planting is a great fallacy as is evidenced by the yield obtained by them. It is not, however, expedient to allow the tree to grow larger than can be thoroughly nourished; indeed, to obtain the fullest extent of fruit the cocoa tree must be pruned in, and in a measure stunted, and the earlier the land can be covered in the better as the weeds, so long as they have light and air, will grow stronger and more rapidly than the cocoa."

Care should be taken to plant in parallel lines and the avenues at right angles with the lines; by this means a better current of air is maintained amongst the plants, and the work of the plantation can be carried on more methodically, and a better supervision maintained. Practice shows that it is better to plant three or four seeds in the space where a single tree is required so as to ensure the growth of one, and when the growth of one is ensured the others, if germinated, can be removed. More than one seed, however, should not be placed in one hole as they are apt to sweat and cause decay. On the subject of manure in the cultivation of cocoa it is said that should it be deemed advisable to apply it, it should be done by

*On young trees in Ceylon they attain a length of over 2 feet.—ED.

* Warmth, surely.—ED.

digging a ring around the tree twenty or thirty inches from the trunk, and burying the manure, which should never be other than pen manure, the nourishment is thus given to the extreme tender roots, which are the points whence nourishment is received from the soil.

In selecting seeds for planting two practices are adopted, they are either taken from the fresh ripe fruits and planted at once or they are allowed to remain in the fruit after gathering till the fruit becomes somewhat dry, or rather the pulp does which surrounds the seeds. The best system is considered to gather the fruits when ripe, and stack them in heaps for a few days, after which the seeds are said to germinate more rapidly.

When the young trees are fully established the spare trees may be removed, and may serve for transplanting into other parts of the plantation, to fill up vacancies. In trimming or pruning the trees, the object to be attained is to have three or four healthy primary branches, and to prune back the others so as to prevent them touching each other, and thus to shut out light and air. The branches should not be allowed to ascend too perpendicularly; the object of this is to keep the trees down to reasonable limits, so that the crops may be gathered with greater freedom. "The cocoa throws out a great many branches, which injure the productive power of the tree. It is most important that they should not be too numerous, nor the foliage too redundant; the one is the result of the other, and together they weaken the tree, and keep off that strength and vigour which the access of the sun's rays and the circulation of air naturally produce. Though the leaves of the tree are the imbibers of much moisture, and the sources from whence, equally with the roots, the tree is nourished, it is essential to allow only the growth of a necessary quantity, in order that the rays of the sun may penetrate, and the air circulate, among the branches. It will, therefore, form the most important part of the planter's duty to prune into form the young cocoa tree."

Most plants are liable, and unfortunately, those that are of the greatest use to man seem specially liable, to attack by insects or fungi, therefore a sharp look out should be kept in all plantations that the cocoa plants are perfectly clean, equally as much from an overgrowth of mosses, lichens, &c., as from insects at the time of flowering; this is especially necessary, and it is also the custom in the best kept plantations, to clear the ground of weeds and other foreign growths, preparatory to gathering the crops. The fruits are ripe and ready for picking when they begin to turn yellow; as the fruits are gathered they are placed, usually by boys and girls, in heaps, where they are allowed to remain for twenty-four hours at least, when they are opened by a slit made longitudinally with a knife or cutlass, and the seeds pulled out by the hand; they are then removed in baskets to the works, where they are placed on a slope to allow what moisture remains to drain off, after which they are placed in boxes for the purpose of slight fermentation, or sweating as it is called. The acid juice that drains off is easily convertible into vinegar or spirit. This sweating process is continued on an average for about 24 hours, but it must not be continued too long, or a sourness is produced instead of the aroma which is intended. Upon removing the seeds from the boxes they should be spread out to dry, and for this purpose they should be exposed as much as possible to a free current of air as well as to the sun's rays. The object of careful drying is to produce a clear, dark red-coloured seed, which is generally considered a test of good quality. When thoroughly dry the cocoa seeds are packed either in bags or barrels, the latter are not only the most secure, but the contents are better protected from external moisture or from being spoiled by coming in contact with other products of a totally different character, which may perchance be stowed away with it in the same vessel.

The various uses of the cocoa bean are so well-known that it is unnecessary for us to go into them here. There is always a demand for cocoa, and more especially for cocoa of good quality; it should, therefore, be the aim of the planter to produce a seed of good size and colour, and with a delicate grateful aroma. These may all be obtained by care and practice. It is generally considered that the best prepared cocoas for use as a beverage are those from which a certain portion of the butter or fat has been taken. The infusion is thus lighter and more easily digested; but it must not be forgotten that the fat of the cocoa bean is not a waste product, but a very important commercial article, both in medicine and for manufacturing purposes, in consequence of its non-liability to turn rancid.—*Planters' Gazette.*

RUSKIN says that linseed oil is one of the most durable of materials supplied by nature.—*Oil and Drug News.*

ARTIFICIAL INDIGO ABANDONED.—The Badische Aniline and Soda Fabrik has abandoned the idea of being capable to produce artificial indigo at a price low enough to compete with the natural color, and therefore has abandoned the experiments made according to Professor Baeyer's process. It remains to be seen, however, if the idea of the artificial production of indigo, although given up as impracticable at present, will not be realized at some future time, as also it remains to be seen if indigo will always be capable of holding its own against the indophenols discovered by Witt and Koechlin, or any other dyestuffs which may be discovered at some future time.—*Oil and Drug News.*

THE BONE TREE.—Captain Maclear, commanding H. M. surveying ship *Alert* writes to the *Standard* last month:—"In August last there appeared in the *Standard* a letter from Lieutenant de Hoghton about the pearl-shell fisheries in Torres Straits. In this he mentioned a curious tree that picked up bones. The account was so curious that I wrote to Mr. Chester, the resident magistrate at Thursday Island, for an explanation, and I think his answer will interest your readers:—'I have made inquiries about the tree, and I find that it grows at Marbiac, not far from Pearson's Station. It is a kind of Banyan, or fig tree, and sends down long vines, or tendrils [roots], from its upper branches; these run along the ground, and twine round any small obstacles in their path, such as bones and other unconsidered trifles. The vines afterwards contract and draw up whatever is attached to them. This is Pearson's explanation of the phenomenon.'"—*Journal of Forestry.*

IPECACUANHA.—The propagation of this medicinal plant is now carried on at the Ootacamund Botanical Gardens with artificial heat. This operation was previously conducted in the branch garden at Burliar 2,500 feet above sea level, but in consequence of the difficulty of securing the services of a trained gardener to live in so feverish a locality, the change to Ootacamund was advised and adopted. In the course of a year the number of established plants was increased from 130 to over a thousand. When once rooted the cuttings can be put out and demand little attention. They require a well prepared compost of vegetable mould, with a liberal allowance of manure. Water must be sparingly applied so as to keep the soil moist but not wet or the plant will sicken and die. With the requisite temperature the cultivation of the Ipecacuanha is a simple matter requiring no skill. So far as we can ascertain there has hitherto been no demand for the cuttings with the stock on hand, the superintendent ought to be able to supply a good number to those desirous of giving the plant a trial.—*South of India Observer.*

PROTECTIVE MOULDING OF POTATOES.—I beg to inform you that since the publication of my little book, I have made further experiments which have confirmed in the most satisfactory way possible all the principal results laid down in my pamphlet, as far as the "protective moulding" and the different soils are concerned. I fear no contradictions from practical field experiments if only they are carried out in exact accordance with my directions. Two things, especially, are necessary, viz.:—1, The earth covering given by protective moulding must be no less than about 5 inches over the upper surface of the uppermost tubers (settling by-and-by to about 4 inches); 2, The protective moulding must be executed before the disease in the leaves has set in, or at least as soon as the first traces can be noticed by a careful inspection of the leaves. A covering of 4 inches is, however, quite sufficient for sandy soils, but for medium and stronger soils 5 inches (to begin with) will be necessary. These suggestions rest on experiments recently corroborated.—J. L. JENSEN, Copenhagen. [We shall be glad to hear more of the results you obtain.—ED.]—*Gardeners' Chronicle.*

UTILISATION OF SEA-WEED.—M. Alexandre Saint Ives is reported to have succeeded, after numerous experiments, in extracting from sea-weed a composition like that of starch and sugar, which is well adapted for the economical manufacture of certain articles of commerce, such as imitation leather, and transparent substances. The sea-weed, previously washed in pure water, or water impregnated with a little lime, or potash, is dried, and then pounded or ground, according to its variety, and introduced into a conical boiler. A soluble substance is extracted by a bath of hot water or steam, when the residue, on cooling, assumes a gelatinous consistency.—*Journal of the Society of Arts.*

VINTAGE OF FRANCE, 1881.—Consul Roosevalt, of Bordeaux, states that the details given by the Minister of Finance, in relation to the wine crop, show a considerable improvement. In 1879, 25,000,000 hectolitres (the hectolitre being equivalent to 22 imperial gallons) were produced in France; in 1880, 29,000,000 hectolitres; while in 1881, there were 34,138,715, giving an increase of 9,138,715 over the year 1879. Notwithstanding this improvement, the yield is still 15,000,000 hectolitres below the average of the ten years preceding 1879. In the ealy part of last year, appearances seemed to indicate the prospect of a very much greater production, but the ravages of the phylloxera, and the abnormal heat which succeeded the constant rains of September and October, to a very great extent blighted the vines.—*Ibid.*

RED SPIDER, ITS CAUSE AND CURE.—To a great many struggling, industrious, and enthusiastic amateurs this universal garden pest is a source of annoyance, and often of considerable loss. Whether it be the imperfectly trained market grower who pays for his learning at the beginning of his career, or the amateur who cultivates Vines or other fruit trees or plants more for pleasure and recreation than for profit, the constant cry is, How can we eradicate or keep down red-spider? It is not always safe to recommend drastic measures to inexperienced people, and yet nothing short of a drastic remedy will oust the enemy from his position. Practical gardeners being fully aware of the dire effects of a serious attack of red-spider, follow the safe maxim that "prevention is better than cure," and therefore give the enemy no quarter. But with the amateur, the enemy comes as a thief in the night, and the sad work of destruction is well-nigh complete before he is aware of the fact. Vines, perhaps, suffer more from the attacks of the enemy than any other plant or fruit tree. In ninety-nine cases out of a hundred the cause is either absolute dryness at the roots of the Vines, or an unhealthy condition, brought about by defective drainage.—*Gardeners' Chronicle.*

A PLANTER OF EXPERIENCE sends us the following information in regard to covering for cinchona trees after shaving, as being cheap, effective, and expeditious. Take common glue, gum, or gelatine, or any like substance, melt by heat with a sufficiency of water, and add Bichromate of Potash or Crome alum. Take any common paper, such as old newspapers, cut up into slips, (by preference 3 inches in width) and paint over or on the solution. Dry in the *sun*. When dried, and the colour of the solution on paper has turned a dirty brown, the paper can be used for the purpose required. Commence covering, as in ordinary bandaging, at the lowest part of the tree, and so on to the highest portion shaved, keeping of course each turn of paper slightly lapping over the last turn, and finish off at the top with a tie of aloe fibre, or thread of old sack. The bands of paper *may* not of course be long enough in themselves to cover the whole of the tree, but one piece can be continued on from the other, if merely commencing as at first. The painted side of paper is of course exposed. I have tried this method with great success, and, if properly put on, the paper will last for months. Potash Bichromate is about 9d per lb. in England, and 1 lb. would be sufficient for thousands of trees, when in solution. Make the gum solution fairly thin, and add to each liquid oz., say 25 grains of the Potash Bichromate. The action which takes place, perhaps you may like to hear, is described as follows:—"Gelatine, aided by light, reduces the Chromic acid of the bichromate to a lower state of oxidation and then enters into combination with a compound chromic acid, produced by decomposition of the acid and the gelatine, the result being the formation of a leather-like substance insoluble in *hot* water." The Potash Bichromate is, I may add, a highly irritant poison.—*Daily Bulletin.*

GUM FROM GREVILLEA ROBUSTA.—In some interesting notes on the Shevaroy Hills for 1881, recently communicated to the Agri-Horticultural Society of Madras by Deputy-Surgeon-General Shortt, the following paragraph occurs:—"Of the plants introduced on these hills, I have to notice a peculiarity as regards the Grevillea robusta—one tree, which is now eleven years old, has for the last two years during the rains produced spontaneously each year 10 oz. of a translucent gum which has no smell or particular taste, is of a pale yellow colour, and mixes readily with water, when it forms a whitish brown-coloured mucilage, and as a paste answers all the purposes of the so-called gum arabic for adhesive purposes. The other Grevillea trees are some two or three years younger, and have not as yet evinced any disposition to produce gum." This statement is a remarkable one, as none of the Proteaceæ were known to yield gum.—*Gardeners' Chronicle.*

COCKCHAFER GRUBS.—A paragraph in the *Indian Journal of Forestry* is to this effect:—It is recorded in the *Revue des Eaux et Forets* that a forest guard, named Beny, has pointed out a good plan of getting rid of cockchafer grubs from his garden. He digs holes about 2 feet in diameter and 2 feet deep, and fills them with stable litter covered over with soil. In June, in a day when the sun is hot, the holes are opened, and a large number of grubs are then found and destroyed. But such a measure would be of very little use in India. In 1881 in Darjeeling almost all gardens were visited by these cockchafer grubs, who eat off not only the roots of bulbs and other flowering plants, but stripped the turf from the banks. The Superintendent of the Botanic Garden made an estimate that he had destroyed about eight millions of them. This year the beetle is not uncommon, and it is much to be hoped that it will take itself off elsewhere to lay its eggs.

A GIGANTIC OLIVE TREE.—A correspondent of the Berlin *Garten Zeitung* states that there is an Olive tree at Bendinal, near Palma, in the island of Majorca, that has a trunk 13 metres in circumference. The tree is of little height, and has few branches. Its fruit is like that of the younger trees. He goes on to say that the Olive trees of Jerusalem are computed to be 2,000 years old, and they are only 6 metres in circumference. How old, then, he asks, may the Majorca tree be? Perhaps not so old as those at Jerusalem, we answer. Countance, in his admirable *History of the Olive*, mentions one tree as having a trunk 12½ metres in circumference close to the ground, and 6½ metres at 1 metre from the ground. This tree stands between Villefranche and Nice, and was a notable tree in 1515. He also quotes another writer, though he does not seem convinced of his veracity, who describes an Olive tree whose hollow trunk was so large that a score of persons could take shelter within it at once.—*Gardeners' Chronicle.*

AMOLE—A PLANT THAT YIELDS SOAP.—These cacti grow on the American continent from Mount Shasta on the north to a similar latitude in South America, and from the Pacific coast to east of the Rio Grande, through New Mexico and Western Texas. The flower stalks are destitute of leaves, but are plentifully supplied with branches about eighteen inches long, from which flowers of white and yellow colors are suspended in the flowering season. The bulbous root is from one to six inches in diameter and from six to eighteen inches long. A saponaceous juice is expressed from the root and the fiber of the leaves* is heckled for the manufacture of mattresses, cushions, and chair seats. The vegetable soap extracted from the root has been used by the Indians, Mexicans, and others for many years as a hair wash, and exceeds in purity our manufacture from animal substances. The preservative qualities of the soap are well known and its use gives the hair a fine natural glow, preventing decay of the hair and entirely eradicating dandruff or other impurities on the scalp. Cattle eat the leaves in the spring as a purgative. And cut into bits and thrown on water where fish abound, the effect is stupefaction of the fish, when they can be easily taken. The price among the Indians and Mexicans, who sell it in Tucson, is five cents for a bunch of two stalks interlaced (mancuerna). For cleaning flannels the amole is found vastly superior. It may be hoped that the manufacture and preparation of amole may become one of the industrial pursuits of the age.—*Tucson Citizen.*

* Fibre of the leaves of cacti? Aloes must be meant.—ED.

TROPICAL CULTIVATION IN QUEENSLAND: THE SUGAR ENTERPRIZE THERE AND IN CEYLON.

Before taking up our specific subject, we may advert to and discuss today the Governor's suggestion, in his Speech to the Legislative Council, of the possible revival of sugar cultivation on a large scale in Ceylon, and the remarks of a correspondent on the subject. Our impression always has been that the sugar enterprize in Ceylon failed, not because the soil and climate were not equal to the production of crops of luxuriant cane, but because the proportion of saccharine matter in the canes produced was so small in proportion to the watery moisture as to render manufacture unprofitable: often impossible. We remember seeing a Mr. Allan in the neighbourhood of Negombo, ladling up a mass of bubbling molasses-looking stuff from a cauldron, and declaring, in a tone of despair that, boil as he would,

Double, double, toil and trouble,
Fire boil and cauldron bubble,

he could not get the sugarcane juice to granulate. That, we believe was, more or less the reason why all the plantations, from the Dumbera one on which the late Mr. R. B. Tytler began life in Ceylon, on to the close of the late Lord Elphinstone's persevering efforts at Paraduwa were abandoned,—as sugar plantations. It is very true that all was not failure. We well remember Mr. MacGregor, who managed Lord Elphinstone's place (now likely to be a success with such "new products" as Liberian coffee, cocoa, tea, etc.,) bringing a loaf of refined sugar to the *Observer* Office, such as could scarcely be excelled. But mere occasional successes, due, perhaps, to abnormally dry seasons, did not enable the enterprize to pay, and so sugar plantations and manufactories with their expensive machinery, were abandoned, all but that on which some of the earliest experiments were made, by the late Mr. George Winter and continued by his son-in-law, Mr. Bowman, in the valley of the Baddegama or Gintara river, above Galle. The near contiguity of this estate (formed mainly of paddy lands), to a steady market for the inferior kinds of sugar, amongst the shipping resorting to Galle, was in the early stages much in its favour, and before Mr. Bowman's lamented death he felt encouraged to import improved appliances, the results of which are the fine crystals now for sale in the local markets. But although the local markets—first of Galle and then of Colombo,—have sufficed to support the comparatively limited experiment at Baddegama, it is clear that operations on a more extended scale could only command success by the growers being able to compete in the markets of the world with the sugars grown on volcanic deltas and in deep rich alluvials in Cuba, Jamaica, Java, Demerara, Mauritius, and other more favoured countries. What the Ceylon rivers wash down in the shape of mineral matter is mainly disintegrated gneiss, and the alluvial matter, apart from the decayed vegetation which it contains, is fertile mainly because of the influence of tropical heat and heavy rainfall. It will grow luxuriant crops of stalks and leaves but after a few crops are removed, its power to mature fruit or to elaborate saccharine matter is largely exhausted. Fertilizing substances must then be applied and the question now is, can sugarcanes in Ceylon, which are common enough as an article of refreshing diet in the raw state amongst the natives, being sweet enough for that purpose, be so improved by the use of guano and phosphates, as to granulate well and yield paying returns? Even the richest soils of volcanic origin require manuring after half-a-dozen crops are taken off the ground. The competition, therefore, would be unequal only against those who have large areas of virgin soil to operate on. This is the case with the Queensland sugar-growers at present. The river deltas are by no means so extensive as they are in many other countries, but still the areas are large. For instance, in the Mackay district alone it is computed that there are over 300,000 acres of land suited for sugar cultivation. The other great consideration is the enormous cost of the machinery required in the scientific manufacture of sugar. To take in canes sufficient to yield 200 tons of sugar, machinery including vacuum pans and *triple effet* appliances, would have to be erected which would cost £20,000; while this sum must be doubled if 500 to 600 tons are manufactured. When we were in the Mackay district we travelled with a Mr. Mackinnon, who paid £90,000 for the Pioneer estate, and, besides the machinery which he found ready to his hand, we believe he has made additions at a cost equal to half the money which he paid for the property. Operations on such a scale are, evidently, not to be thought of at present in Ceylon. If experiments are to be tried, they must be tentative and modest. We should not like to speak dogmatically, but we must repeat our belief that (visitations of insect and fungoid plagues excepted), in our soil and with our climate, we can *grow* luxuriant canes of all the best descriptions. The question is not growth but chemical constituents. If our canes could be brought to yield juice, of which ten per cent would shew sugar by the test of Beaume's saccharometer, and if we could get 20 to 30 tons of such canes for each acre, then we might go ahead. But as a preliminary experiment, it would be well to have specimens of the canes grown in the wetter and the drier parts of Ceylon analyzed and tested for sugar. Sugarcanes which taste sweet enough when sucked for the sake of the juice, might be found woefully wanting in the saccharine constituent when so proved. If, on the other hand, they stood the test, then it would be clear that the cause of former failures must be looked for mainly in the superabundant moisture in our atmosphere, and a remedy might be discovered in the modification of buildings and machinery. We are by no means sanguine that Ceylon will ever take her place amongst the sugar countries of the world, but, as we can remember the time when the successful growth and manufacture of tea in our island was believed to be impossible, because, amongst other reasons, tea prepared for the Messrs. Worms, cost £5 sterling per lb., we certainly feel that the interesting question started by Governor Longden, in consequence of his past connection with sugar colonies, ought to be fully considered and investigated.

In order that at this juncture of renewed discussion of the subject our readers should be placed in possession of all available information on the subject, we extract from Fergusons' Handbook of Information for 1876-78, the carefully compiled summary of the history of Sugarcane Cultivation in Ceylon, a history marked by failure and disaster apparently in every case save that of the carefully conducted and longcontinued experiment by the Messrs. Winter and Bowman near Galle. It would be interesting to know to what extent they have used fertilizing substances and of what kind:—

SUGAR IN CEYLON.

The systematic cultivation of the sugarcane was, previous to the present century, attempted twice on a large scale in Ceylon, in the neighbourhood of Kalutara, and both times occasioned great loss to those engaged. The late Mr. Winter first, in the present century, introduced cane, planting a little near Kalutara in 1826, and growing it and manufacturing sugar, but abandoning the

attempt on his removal to Galle. At Baddegama, a Bengal indigo planter put down an acre of Otaheitan cane obtained from Mauritius along with his indigo (which proved a failure) and his estate being purchased by Mr. Winter in 1840, the latter turned his attention to sugar, which grew most luxuriantly. In the Central Province, Mr. Tytler was employed to plant sugar in Dumbara for Messrs. Ackland and Boyd in 1837-40 and the Peradeniya sugar estate of Messrs. Baring Bros. was opened in 1840. West Indian and Mauritius planters engaged in the industry with plenty of experience and capital, chiefly in the neighbourhood of Galle, as well as of Negombo and even of Kandy; and between the years 1842 and 1846, the following large sugar plantations were formed in the Southern Province at a great expenditure of money :—

Oodagama on the Gintara river, 30 miles from Galle, by the Baron Delmar. Habangam on the road to Matara, 12 miles from Galle, by the Baron Delmar. Telicada on the Gintara river, 9 miles from Galle, by Messrs. Faulkner, a Liverpool house. Kohila Wagura, on the Ambalangoda lake, distant 18 miles from Galle, by Messrs. Tindall and Co. Paradoowa, on the Matara river, by Lord Elphinstone. Wilpita, on the Matara river, by Mr. Greg. Mr. Robert Craig who made a fortune in coffee growing in Kaduganawa, lost it all in trying to produce sugar near Galle.

In addition to these, small plantations were opend near the Gintara by Mr. A. Orr and at Waterakka by Mr. Palmer, but the result was again disastrous, and it was finally proved that, while the cane will grow most luxuriantly, the climate is too moist to permit of the sap crystallizing or yielding a sufficiency of produce save in the form of raw canes. One by one within from five to ten years the larger estates were abandoned and sold at a heavy sacrifice ; Telicada, Shandon, cost Messrs. Faulkner £30,000 and was sold by them in 1852 to M. Montclar for £550, and he again sold off the land in small lots. There were several sugar plantations also formed in the Western Province :—at Dalloopatgedera, between Negombo and Kurunegala, commenced by Mr. Elliott, and purchased by Mr. G. Fraser, an experienced West Indian sugar planter ; and at Katukanda, Dambawinna and Etgala or Perth ; but in every case save the last, coconuts speedily took the place of the cane. In 1860, the only places where any systematic cane-growing was still attempted were at Paradoowa (Lord Elphinstone's, managed by Messrs. Mac Gregor and Hume), Baddegama (Messrs. Winter); Etgala or Perth near Panadura (belonging to Bombay Parsees, and managed by Mr. Gay); and Peradeniya, near Kandy (Messrs. Baring Bros, managed by Mr. Vallance). Within a few years however, Paradoowa was sold to Moormen who parted with it to Mr. J. W. Home, who started there his first speculation in Ceylon, a grand garden of bananas or plantains, the fruit and fibre of which were to make the enterprizing cultivator's fortune, until a great flood came and swept all the trees and his hopes away. Perth has been converted into a coconut plantation. Peradeniya sugar-land has been gradually sold in lots, and Baddegame alone remains with a small acreage under cane, * the cultivation and manufacture of which are combined with several other industries, more particularly essential oils from cinnamon and lemon grass. The natives manufacture great quantities of "jaggery" sugar for local use from their palm trees, chiefly the kitul (*Caryota urens*) and palmyra, and they have also the sugarcane very freely growing in their gardens, which adds to the means of subsistence very considerably, a favorite accompaniment for a Sinhalese pedestrian on a journey being a stick of sugarcane over his shoulders, at which he munches occasionally as he trudges along. If the natives paid more attention to the growth of cane especially in the Southern Province, and allowed it to be manufactured at a European mill, a good deal of course sugar might still be obtained for the local market. There are probably a few thousand acres still under sugarcane chiefly in native gardens. The annual import of sugar into Ceylon are now equal to :—candy and refined 5,606 cwt. valued at £67,023 ; unrefined 13,701 cwt. at £20,552 ; and palm and jaggery sugar (from India, better made probably than in Ceylon,) at £4,182.

Of cane sugar the world's production is given at 2,140,000 tons —of which one-third is raised in Cuba; one-sixth in Puerto Rico, and the rest of the West Indies (British, Danish, and Dutch); 200,000 tons in Java ; 170,000 in Brazil; 130,000 in Manila ; 120,000 in China; 100,000 in Mauritius, and the same in Martinique and and Guadaloupe; Louisiana 75,000; Peru 50,000; Egypt 40,000, also Central America and Mexico; Reunion 30,000: British India and Straits 30,000†; Honolulu 10,000 and Australia (Queensland and New South Wales) 5,000 tons.—Nearly a million tons are consumed in the United Kingdom, and rather more on the Continent of Europe ; in North America 750,000 tons; in Central and South America 150,000; West Indies 50,000; Africa 50,000 ; Australasia 100,000 tons; Asia 1½ million tons.

In the Madras Presidency—chiefly Bellary and Ganjam—there are 30,000 acres under sugarcane.

A series of practical papers on sugar cultivation appeared in the *Ceylon Observer* of 1841 from the pen of Josias Lambert, Esq., F.G.S.

SINHALESE LABOUR FOR QUEENSLAND.

The following is an extract from the Bundaberg correspondence of the *Queenslander* :—

In about a dozen places around here sugar-mills are being erected as fast as labour and material will permit. Avoca is nearly finished, Fairymead is fast approaching completion ; whilst in the Wongarra Scrub much headway is being made. The cane on the whole looks splendid, only in low-lying situations showing any sign of being affected by the few frosts we have had. Towards the coast the youngest cane is as green as a leek, giving promise of huge returns. The refinery and pipes leading thereto will be ready to commence operations early next month. Many Polynesian labourers are needed to fill up the gaps that will be made by expireeboys in August. Where they are to come from is a serious difficulty. Messrs. Nott Bros., of Windermere, are not going to trust to chance, but have taken time by the forelock by treating for 100 Sinhalese, which will arrive by the incoming mail-steamer. It is their intention to obtain regular supplies of these labourers for themselves and others. The planters are much pleased with Messrs. Nott's action in thus helping them out of a most unfortunate dilemma. It is only those who live in sugar districts north of Brisbane, who can form any idea of the value of reliable labour in developing this important industry. Even with all the outcry against Polynesians, it is almost impossible to get anything done by white labour ; to get necessary work done in a hurry is out of the question. Every branch of skilled artisans here is crowded with work, and numerous annoying delays and losses occur in consequence.

In an article on "Pacific Island Labour" in the *Queenslander*, we have the reason more fully given why the sugar Planters of Northern Queensland are indenting on Ceylon for Labour :—

What causes have led to the shortness of the supply of islanders? The islands are not depopulated. They are better known than they were. Trade with the islands from both Sydney and Melbourne has increased. Whence then this difficulty? The 17,000 islanders which at various times have been introduced into Queensland represent a very small proportion of the island population. Of these nearly 10,000, up to the end of 1880, had been returned to their island homes Having become acquainted with us and our ways having served their apprenticeship on our plantations it was supposed that these return labourers would act, as missionaries of this industry, that having acquired a knowledge of the world they would induce their friends and relations to cast in their lot with us, and thus rise above the simple savagery of their native homes. It must be admitted that there are some grounds for disappointment. The natives do not flock to our recruiting vessels, as it might by some perhaps be expected that they would. Too frequently the every reverse of this is the case. Agents are not unfrequently killed. The recruits which are obtained are often weak and undersized—mere youths—whose services are of no great value to their island superiors. What are the causes of our comparative failure in dealing with these interesting people? It must be admitted, we fear, that we have not made the best of our opportunities. They have taken their boxes to their islands. These contained a few slop clothes which would soon wear out, some useful tools occasionally, axes, adzes, and saws, and there was invariably a gun, a Snider rifle, and ammunition. And now it is quite a common thing for boats approaching some of these islands to be fired at indiscriminately.

NITRIFICATION IN SOILS AND COFFEE CULTURE.

No more burning of weeds but rather the digging of them into the soil on coffee plantations with the addition of lime and all the prunings that can be availed of, should henceforward be the order of the day. It is evident that a great deal more must be

* In the latest Government Blue Book four sugar mills are still reported from the Southern Province, but we doubt if they are used, unless it be the one at Baddagama.—COMPILERS.

† The figures for India must be far below the mark considering how largely sugar enters into the food of the Hindoos.—ED.]

done with lime so soon as the railway is open to the higher districts, and we believe more thorough pruning and utilization of all green stuff as well as the digging of the soil will be found to repay on every plantation where the coffee is in fair heart Dr. Taylor of "Science Gossip" writes :—

As far back as a quarter of a century M. Pasteur suggested that the process of nitrification going on in soils and waters might be due to the agency of an organism. The researches of Schlosing, Muntz and Warington have now proved that this is the case, and that the organism is a *bacterium*. This *bacterium* is present in all fertile soils, and under proper conditions of temperature, moisture, supply of oxygen, and the presence of a salifiable base, it is engaged in continually converting ammonia and nitrogenous organic matter into nitrates. These nitrates are the chief sources whence our crops obtain their nitrogen. Nitrification in soils has been discovered to take place most rapidly in hot weather. The *bacterium* which thus produces nitrification of soils is only one of a great number of the lower forms of life which are just now engaging the attention of scientific men. Amongst others are the life-histories of the organisms which bring about the changes occurring during the souring of milk and the ripening of cheese. "Beet-sickness"—that is, the unaccountable withering away and shanking of the beet plant at a time when it ought to be rapidly growing—has been traced to the presence of a nematode worm.

Most agricultural chemists regard the vast stores of nitrogen contained in our atmosphere with envy. How are those supplies to be tapped? To the man who can solve this problem wealth and fame are open. Some plants, chiefly leguminous, have partially discovered the secret. Professor Ville, the distinguished French agriculturist, advises the European Governments to unite and offer a large reward for the discovery, so as to tempt experimentalists. But the discovery will be made eventually without any inducements of this kind. Already it has been found that if 1 per cent of magnesium sulphate be added to any manure-heap, the nitrogen is increased by absorption from the atmosphere.

PROPOSED FORMATION OF A COFFEE SYNDICATE.

We lose no time in publishing and drawing attention to a letter from Mr. Bourdillon, the Secretary to the Travancore Planters' Association, on the question of a Coffee Syndicate, so that there may be the opportunity for consideration of the scheme at the approaching meeting of the Ceylon Planters' Association. The arguments used by Mr. Bourdillon are such as have always seemed to us to be forcible and conclusive. We can see no possible reason why a distinction should made in legislation between tea and coffee, guarding with strict jealousy the purity of the one, while free scope is allowed for the adulteration of the other. Even granted that to some coffee may be distasteful, unless its native strength is modified by a mixture of chicory, surely the two articles can be sold separately, the consumer mixing to his taste. If our legislators profess that this would be entailing trouble on the consumer from which the benevolent grocer ought to be allowed to save him, then we reply, "at least, insist on the grocer inscribing on his packets the proportions in which they contain the genuine article and the adulterant." The true reason why such arguments are not listened to is that legislation is influenced more by the powerful dealer interst than by the coffee-drinking people or their friends. From the contant discovery, invention and advertisement of date coffee, pelotas coffee and other substitutes, the impression might fairly be received by onlookers that the genuine coffee was a poisonous impostor who ought to be as much superseded by innocuous, if feeble beverages, as Haus Andersen's character in the tale was by his own shadow. Coffee, in truth, has been so put in the background and overlaid by things which come like shadows but do not so depart that, although the fragrant berry is not a new article like Indian tea, yet there is a real necessity of proving to the public the existence and the merits of genuine, unmixed, unadulterated coffee, which is as superior to imitations and substitutes as Stilton cheese is to Dover chalk. The Ceylon planters are the best judges of what will subserve their interests, and it is true that at present they are likely to find a ready market for all the colory plantation coffee their much-tried bushes will bear. But as we have not given up heart or hope, even in regard to our "sick man," King Coffee, so we think this idea of a Coffee Syndicate for the purpose of exhibiting and pressing the claims and merits of genuine coffee is worthy of consideratied and support.

PLANTERS AND THEIR AGENTS IN S. INDIA.

A 'Garbler' writes :—

"Please allow me to put 'Dry Cherry' through an allegorical peeler, and try and make something of him.

1. Would 'Dry Cherry' kindly state the weight he dried his coffee down to on the Estate? There is not one Planter in fifty who sends his coffee down to his Agents perfectly dry and fit to peel. Planters have few facilities for drying coffee in Wynaad, such as large barbecues, &c. The mountain dews and mists are also fatal to proper drying. Could the coffee be dried on the Estates, coffee-curing would cost much less than it does at present. I should also like to know how he makes out that the samples he weighed on the estates are bulk for bulk lighter than after it was cleaned and put on board ship? How can he compare the two weights, of parchment when it leaves the estate, and that when it has been dried, peeled, sized, garbled and packed?

2. He says he took one lot of coffee and sent it down to the Coast in three consignments under three marks. I will prove that what he sent down could not have been parchment coffee, as no parchment, unless it was utter refuse, would turn out 122 bushels to the ton. 95 is about the average. It could not have been cherry, or mixed, as that averages 140 to 150 bushels to the ton, and never turns out so low as 98. What could it have been? It must have turned out to be some new produce of Fair Wynaad, certainly not coffee; but, happy thought, it might have been date coffee.

3. He says the coffee that he measured on the estate turned out exactly the same number of bushels when it reached the Agent. He is evidently a lucky dog and had an honest cart contractor; but given that the contractor is honest, and the coffee fairly dry when sent off, I will, as Mr. Dry Cherry wishes to make a moderate bet, eat his best hat if that coffee does not turn out the same number of bushels when it arrives on the coast as when it left the estate; should it not do so of course Mr. Dry Cherry would have to eat my best hat, a fine old beaver by Lincoln and Bennett. I guarantee it would prevent the tonic gurgulations which he appears to be suffering from, and which are, strange to say, in his case caused by excessive drainage. With myself and others, when we get an attack of tonic gurgulations (which of course is never, or, well, hardly ever) they are caused by excessive dampness in the interior of the body; Exshaw No. 1, or gin tonic, taken in too large doses will produce the gurgulations referred to. The only dry drink I know of which will cure them is 'Dry Monopole,

but I am wandering from the point again. With reference to the sale, &c., of coffee, if a Company were started for that purpose, I doubt very much whether they could do things cheaper, and as to the rates of freight he must well know that if he wishes to do so, he can ship his coffee by the British India New Line, which is endeavouring to do things cheaper than the coalition, whose rates of freight have always been as low as other lines of steamers. As to curing charges, R50 per ton at first sight appears to be a high price to pay, but it must be remembered that for eight months in the year expensive works, necessary for curing coffee, and containing valuable machinery are lying idle; the same may be said of the greater part of the establishment of clerks, who have to be kept on all through the year doing little or nothing. Let 'Dry Cherry' start a Company and go and borrow money if he can get it from the Banks. There is nothing to hinder a planter from doing that now, except the one important fact, that the Banks would not advance the money. The Coast Agent will not accept a greater risk than the Banks, and therefore rightly expect a higher rate of interest on his money. I envy 'Dry Cherry' at his being able to put down R20,000 on the nail; there are few planters and even much abused Coast Agents who are able to say that in these hard times. In concluding my letter I must state that in writing as I have done, I do not intend to run the planters down. They are the jolliest and most hospitable fellows out, but when one of their number runs the 'Garblers' down they must defend themselves, and therefore 'Dry Cherry' has been put through the peeler."—*Madras Mail.*

TEA IN CACHAR.

The season promises to be a peculiar one, and the general cry is for rain, and, judging from general appearances, one-half of the paddy lands will not be put under crop this year. We do not anticipate, even in the face of this, a very material rise in prices, as none of last year's crop has as yet been sold, and a very large portion of the previous year's crop is still housed in the villages. The present prices are ruinous to the cultivator, so that a slight rise will do no one any harm. The rainfall is now from 12 to 15 inches short of last year.

We are now past the middle of the season, and so far as regards Cachar, the increase in outturn will not be very much. Most of the gardens on the north bank of the Barak are far behind, whilst on the south bank they are equally far ahead, and allowing for increase in area coming into bearing, we do not think that the increase for export over last year will be more than half-a-million pounds, but the teas are of a decidedly better quality than last season's. Notwithstanding, they are fetching very much lower prices, the brokers do not attribute it to the market; consequently the poor planter is blamed.

Tea must be produced locally for five or six annas, and in Calcutta charges must be reduced to say 1½ annas per lb., in order to make it a thriving industry, and one which will pay, and new gardens must be opened out on a very different basis to what they were in former years. We purpose, in succeeding numbers, to enter upon the subject of opening out a new estate, with an object to make it pay at a price not exceeding nine annas per lb., and to show that even that will give a handsome return, provided economy is exercised in opening out, and *indenting* for what is only necessary, instead of as in former years having the godowns in the factories crammed with machinery of all sorts and sizes, which is not at all necessary. We have just got most seasonable rain, and it looks as if it would continue. There is a long lee way to make up, as much as thirty-five inches in some places.—*Indigo Planters' Gazette.*

CEYLON TEA IN AUSTRALIA.

Mr. A. B. Inglis, late of the Firm of Begg, Dunlop & Co., of Calcutta, and member of the Governor-General's Council, in the course of extensive journeyings before settling down to business in London, returned from a trip to Australia by last steamer, and we had the pleasure and profit of comparing notes with him about Australia, India and Ceylon. As it was he who induced Mr. Bernard, the present Chief Commissioner of Burmah, when Secretary to the Government of India, to regard favourably the idea of a Government grant to the Calcutta Tea Syndicate, whose operations in Melbourne, through the Firm of James Henty & Co., have been so eminently successful in introducing Indian tea to the Australian communities, he was, of course, much gratified at what he found had been done in the Southern Colonies, by the Firm referred to in Melbourne and by his own able and eloquent brother, "Maori" Inglis, in Sydney. With reference to Ceylon tea seeking a market in Australia, we told Mr. Inglis that, while most anxious, in return for all that Mr. Moody had done for Ceylon tea, to induce all whom we could influence to send tea for sale to Messrs. Henty & Co., complaints had reached us regarding the heaviness of the Melbourne charges as compared with those in account sales from London. Mr. Inglis told us that similar objections were raised by the Calcutta Syndicate and that now the charges were lowered in their case to 4 per cent. It seems that the Melbourne custom has been for purchasers of tea even at auction to get long credit, and that in the introduction of a new article it was felt that the purchasing brokers must be conciliated. If consignors wanted their money at once of course discount had to be charged and this has been specially complained of as heavy. We have no doubt, however, that on proper representations being made, all such difficulties will ere long be removed, and we trust that Ceylon tea will yet be as well known and as much approved in Australia as it now is in London. It will be of great importance to the future of our young and promising industry that it should have many markets to go to.

AGRICULTURE ON THE CONTINENT OF EUROPE.

(*Special letter*).

PARIS, 26TH AUGUST 1882.

M. Fleischer, of the Agricultural College of Bremen, has been conducting, since three years, experiments on peaty soils, to test the efficacy of partly soluble phosphates and the superphosphates. The former proved the more beneficial; the phosphoric acid readily soluble is not absorbed by the humus-earth, so consequently disappears quickly from the stratum where the roots exist; indeed this acid exercises a deleterious effect in soils already acid. Bone-dust, guano, gelatinous phosphate, and phosphorite, in a word, all substances containing soluble phosphoric acid yielded the same results, on old as well as new peaty soils. Hitherto it was believed that peat soils contained a good deal of sulphuric acid, which acted in the recalcitrant phosphates. M. Fleischer shows that the energetic action is due to humic acid.

Potash is a fertilizing element whose restoration to the soil is indispensable, as it is carried off by crops in considerable proportions. This restitution becomes the more imperative, when plants of the leguminous family, such as clover, disappear to be replaced by moss. Unwashed wood-ashes, containing 6 to 8 per cent of potash and 3 to 4 of phosphoric acid, often produce marvellous effects; the moss disappears, and the clover and similar plants take its place.

M. Rimpeau at Schlanstedt, and Prince William at

Schaumbourg, have been occupied with the influence of potash on the production of sugar in beet. After the bedding was cleaned in the morning, the boards were strewn with 1 cwt. of kanite, and ½ cwt. of gypsum, per two tons of soiled bedding: the latter on being removed was allowed to steep in putrid urine, and in time applied at the rate of 11 tons per acre, to a marly soil. The manure, enriched with kanite, produced a slight augmentation in yield of roots, over the gypsum combination. The salient fact elucidated by Prince William on his estate in Bohemia is that chloride of potassium exercises no essential action in humid years, while in dry seasons 1½ cwt. per acre secures an increase of 3 tons of roots per acre; that the salt of potash acts less by furnishing that element to vegetation than by its absorbing and retaining humidity for the plant.

The Prussian Minister of Agriculture appointed Messrs. Königet Kranch to study the changes which water undergoes, and the action it produces when applied in irrigation. The experiments took place at Munster, where several systems of waterings and drainages are employed. About 5 per cent of the water employed, on an average, escapes by the subsoil; in a soil destitute of fissures, &c., the loss is less than is generally imagined: heavy and persistent rains do not penetrate the soil beyond 12 inches, and humidity entered in proportion as the surface presented cracks, or was honeycombed by moles, &c.; drains flow only when the rain has ceased, and discharge waters that have arrived from distant points, due to accumulation in impermeable strata, &c. The more the temperature of the water employed for irrigation is elevated, the more beneficial it is for vegetation: the water in flowing over the meadow cools quickly if the air be cold, while if the contrary, it augments rapidly. Even in cold seasons, the water possesses a sensibly higher temperature than the soil, thus preserving the latter warmer for a longer time. The fertilizing action of irrigating water depends less on the absorptive properties of the soil upon the matters held in solution than on the precipitation of the matters in suspension, and the direct absorption of these nutritive elements by the roots of plants. The only nutritive element retained by the earthy particles with persistence is potash, and the water is deprived of the mineral matters it contains in proportion as the temperature of the soil, of the water, and of the air, augment. It is from the water directly then that plants extract nutriment, save potash, which the soil seizes upon: thus in the seasons when vegetation sleeps, the water escaping by drainage from irrigated meadows is poorer in potash owing to absorption by the soil, than the irrigating water itself. The application of potash salts to grass lands under irrigation produces an elimination of the lime in the soil; the equilibrium becomes re-established when the potash ceases to be applied. Similar observations apply to phosphoric acid. The irrigating water introduces oxygen into the soil, similarly as does tilling the land: it reduces the acidity also of the soil, as the water escaping by the drains is proverbially richer in acid combinations.

Belgium has started a new idea, that of founding an agricultural *station*, or technical college, exclusively devoted to the conduct of scientific and practical experiments connected with the growth and manufacturing of sugar beet.

The Pasteur process of vaccinating sheep as a preservative against *charbon*, after proving a success in the north of France, has turned out the same in the warm south. The point on which attention is now fixed is for how long—six, twelve, or thirty-six months—does the efficacy of the pock endure? Time of course will settle the point. Native Barbary sheep are proverbially known to resist charbon, but when crossed in France that immunity disappears.

That other scourge, the phylloxera, continues to extend its devastations: authorities are commencing to make up their minds to expect that malady as permanent, and requiring to annually employ insecticides against it, as sulphur is for the oïdium. The best inseeticide is still sulphuret of carbon, joined to fortifying manurings. Irrigations during autumn are excellent, and M. Jules Maistre even practises the same during summer.

The prospects of the beet crop are good: the density of the juice is remarkably satisfactory: only continued moist weather can make an alteration.

INDIAN TEAS.

[The indefatigable Mr. Moody, of Messrs. James Henty & Co., has circulated the following information with a catalogue of 1,253 half-chests of Indian tea which were to be sold on 21st Sept.]

The following Extracts are from a valuable Manual just published in London:— *

One of the most remarkable circumstances in connection with the development of the tea trade is the rapidity of the increase in the production of Indian tea. It is within the memory of many still engaged in the trade that the idea of India being one of the most important branches of the business would simply have provoked a smile, and yet, in the year 1881, there was imported 44,585,000 pounds of Indian tea; and, large as this quantity is, it failed to keep pace with the consumption, which for the same year was 48,342,000 pounds. This is an increase of tenfold in fifteen years, and even in weight is nearly one-fourth of the entire deliveries of tea; while, should money value be taken as the test, the proportion would be much larger, as the price commanded by Indian tea is considerably greater than that of China.

The taste for Indian tea is rapidly increasing; here and there some even prefer it by itself. In Belfast and other parts of the North of Ireland scarcely any China tea is consumed, the trade being nearly all confined to the stronger Indians; but the greater portions of the English people like in every blend at least half China tea.

No China teas possess such sharp piquancy, such great strength, and such pronounced yet delicate flavour as the better descriptions of Indian teas. To obtain the perfection of these qualities it becomes essential to use the best Indian varieties.

The cultivation of tea is, in India, much more a matter of science than it is in the Celestial Empire. The Chinese, from time immemorial, have grown their teas on every little available space—sometimes on hillsides, sometimes on patches of land comparatively barren. They have used little or no manure; in fact, the son has followed in his father's steps without attempting to excel.

On the contrary, the growth of the tea industry in India has been fostered by many experiments—experiments as to the climate most suitable to tea-growing, as to the soil most congenial to it, and the manure by which it is most nourished; experiments as to the best methods of manufacture, and also experiments to ascertain the best kind of plant to cultivate. All these problems have been solved to a certain extent, but there is no doubt much progress will still be made.

When, therefore, we consider the difference between a system of cultivation so barred to progress as that of the Chinese and one so enterprizing as that of the English in India, we cannot wonder that, while Indian tea has been advancing greatly in public estimation, China tea has made comparatively little progress.

There is one remarkable difference between Indian and China teas, and that is, while first, second, third, and fourth crop China teas are different in character, and respectively inferior the one to the other, there is nothing in Indian tea to proclaim its relationship to any particular crop or gathering.

The following are the principal districts from which our supply of Indian teas is obtained:—

Assam	Hazaribagh (Chota Nagpore).
Darjeeling.	Chittagong.
Cachar and Sylhet.	Neilgherry (Madras).
Kangra.	Dooars.
Dehra Dhoon.	Julipg[illegible]ie.
Kumaon and Simla.	Rangu[illegible]

* "The Art of Tea Blending: a Handbook for the Tea Trade."

ASSAM.—Indian teas from the district of Assam are nearly always strong and pungent, the brokens, in addition, being thick and rich, The colour of the infused leaf is a ruddy brown, with a tendency to red. The dry leaf is a dull, greyish black. The finer sorts are evenly curled, and abound with Pekoe tips.

Assam is the home of the indigenous plant, and its hot, moist climate and rich soil are nearly perfect for tea-growing.

DARJEELING.—Darjeeling teas are full and very flavoury but are not so pungent as Assams. The infused leaf is tender and bright. The dry leaf is blacker, but, taking the average, is scarcely as tightly twisted as that of Assam teas.

Darjeelings from the Terai (the Terai is below Darjeeling) are probably the best teas that are brought to England; for full flavour and rich strength they are unequalled.

Occasionally Darjeelings are found that do not possess the flavour for which the district is justly famous. The tea then is soft and insipid, and is useless for increasing the flavour of a blend. Most of the plants in Darjeeling are from China seed.

CACHAR.—Teas from this district are in character between the Assam and the Darjeeling. They are not so pungent as the Assams, nor are they as flavoury as the Darjeeling, but neither their strength nor flavour is to be despised. The leaf is blacker than the Assams. The liquor is rather soft, and occasionally fruity, with a tendency to be slightly burnt. The majority of Cachar trees are hybrids.

SYLHET.—Sylhet produces teas that are similar to those of Cachar, but are more pungent.

KANGRA.—Teas grown in the Kangra Valley are fine, delicate, and aromatic. Their infused leaf is very bright, and the flavour is even considered superior to that of the Darjeelings, but unfortunately they are often thin.

DEHRA DHOON.—Dehra Dhoon teas are mostly thin, high burnt, and rather sour. Occasionally the flavour is rather earthy. They are not very much sought after.

KUMAON AND SIMLA.—These teas are somewhat similar to Kangras. The are very flavoury, and sometimes rich, but are not unfrequently thin, and occasionally the flavour is not of a very high order.

HAZARIBAGH (CHOTA NAGPORE).—The infused leaf of these teas is very bright. The liquors are fresh and flavoury, but also weak and sickly.

CHITTAGONG.—Chittagong teas are strong, thick, and almost nutty in character. They are good, useful teas, and, for their great strength, are in considerable demand.

NEILGHERRY (MADRAS).—The Neilgherry Hills produce fancy green teas. The black teas from these hills are, perhaps, the most inferior of all Indian teas. When Neilgherry teas were first imported the flavour was decidedly objectionable. It has now slightly improved, but is still far from perfection. The liquor is thin, and the dry leaf black and tippy. These Neilgherry teas from Madras must not be confused with the Assam Neilgherry teas [? ED. C. O.] which are strong, rough, and pungent.

DOOARS.—The teas produced in this district are similar in character to those of Cachar, but, being considerably stronger, are more valuable for blending.

JULPIGOORIE.—Julpigoorie teas have a very bright in fused leaf, and a thick, rich, but rather soft, liquor.

RANGURI.—The infused leaf of this is also bright. The liquor is fine and fresh, but thin and inclined to be sickly.

SORTS OF INDIAN TEA.

In the manufacture, Indian teas are generally sorted into the following classes—

Flowery pekoe	Broken orange pekoe
Orange pekoe	Do. pekoe
Pekoe	Do. pekoe souchong
Pekoe souchong	Do. Souchong
Souchong	Do. mixed tea
Congou	Fannings
Broken flowery pekoe	Dust

"A note at the end of the catalogue is to this effect:—The whole of the Darjeeling teas being mountain grown, are suitable to drink alone; the broken kinds and other district teas, are fine mixers.

COFFEE AND MR. STORCK OF FIJI:

HIS CARBOLIC ACID VAPORIZATION PROCESS FOR THE DESTRUCTION OF HEMILEIA VASTATRIX.

We print on the following page a letter which Mr. Storck has written from Fiji about his carbolic acid vaporization remedy for coffee leaf-disease. As we anticipated, a "perfect cure" has not yet been discovered. On the contrary, Mr. Storck has discovered that his previous dilutions were rather mild for the formidable pest he had to deal with. The process, therefore, is still in the tentative stage. Mr. Storck now uses improved evaporating vessels and has increased the proportion of acid to water to 25 per cent of the former. The vapour then becomes so powerful that it "eats" away the fungus, not only without destroying the leaves but without injuring the more delicate blossoms! And this is not all. We understand Mr. Storck to insist, in the face of what Mr. Ward so strongly asserted, that the odour is fatal to mycelia however snugly ensconced in the interior of the leaf cells. The statement seems to indicate that with a solution of 25 per cent of carbolic acid to 75 of water, placed in proper evaporating vessels, the disease can be extirpated, from spore to root—wherever the odour can be made to penetrate. Of course Mr. Storck will follow up his experiments where he began them, and we shall be delighted beyond measure to learn that one or more estates in Fiji have been freed and kept free of fungus by the constant presence and action of the vapour of carbolic acid, a vapour, happily which promotes sanitation generally, and which, as it does not injure blossom, is not likely to affect the fruit except for good. Taking it for granted, which we certainly do, that it would be necessary to keep the vaporizers constantly supplied (local experiments have shewn conclusively that they become exhausted, more or less quickly) the great question now is what would be the cost of vessels, material, attendance, &c.? If the remedy proved as efficacious as Mr. Storck expects and if it were very generally adopted, no doubt the quantity of carbolic acid required might be after a time considerably lessened, and in any case carbolic acid is not an expensive substance and could be obtained in large quantities at a moderate cost. The result might be that whole districts, perhaps the entire hill country of Ceylon, would be subjected to a constant process of disinfection and deodorization, with no slight effect on bacteria in the soil and in diseased human or animal lungs, as well as on the fungi infesting the coffee leaves. We need not, of course add that tea, cinchona and other products would, by the same agency, be probably freed from insect pests. At this juncture, perhaps gentlemen who have locally tried experiments with the vapour of carbolic acid will relate their experiences. Gentlemen like Dr. Trimen and Mr. George Wall have offered the objection that carbolic acid is not sufficiently volatile to be effective, but, apart from Mr. Storck's experiments, we know at least one gentleman in Ceylon who has come to an opposite conclusion to that of the scientific authorities named. After the failure of Mr. Schrottky, for failure, we fear, the result must be called, we are not, we confess, over-sanguine. But we hold our mind open to conviction, and we are ready to hail the man who really succeeds in effectually and permanently curing our coffee trees of the most terrible disease which ever attacked them, as one of the greatest benefactors of Ceylon and of the coffee producers of the Eastern world.

MR. STORCK'S CURE FOR COFFEE DISEASE.

Upper Rewa, July 4th, 1882.

DEAR SIR,—Since I, a twelvemonth ago, established the first experiment with my "method of permanent vaporization," I have learned a great deal on the subject, and will now give you a summary of my experiences and the final results of the treatment. An account of the first stage of my experiments has already appeared in print, and I, therefore, proceed with a sketch of what followed.

With the low density of the fluid mixture and its vapors I attained certain results which drew my attention forcibly to the influence of the vaporized atmosphere upon the *mycelia* of both the already rust-bearing spots and those still in formation within the tissue of the leaves. Although vast numbers of the spores perished in the act of germination, I could not shut my eyes to the fact that a small proportion escaped, as proved by the reappearance of pinspots on new foliage. Of these pinspots many again died under the treatment, but the survivors grew laterally, were greenish yellow in colour, owing to the comparatively large areas of live green tissue among the branches of the mycelia, as seen under the microscope. They grew and changed their appearance very slowly, seldom produced healthy spores, and generally perished with the leaf without producing any. Leaves so affected would live for many months. Several occasions, however, when the treatment was purposely interrupted, and the density of the fluid and vapor sank below a certain level, those inert-looking spots would develope red rust, usually around their edges, although I had in the meantime raised the density by degrees to 7 per cent and 10 per cent of acid. This demonstrated that the mycelia, even though temporarily barren under the vaporized atmosphere, have the faculty of recovering through forming new lateral buds and branches and are not actually dead until brown and dry. The signal success I had with a Liberian tree under peculiar circumstances and taking into account the periodicity of the consecutive stages of the development of the fungus, have since determined me to use, what I had before indicated as a safe limit, 25 per cent, but in fortnightly applications only, which change in my tactics has been followed by the best results. I have, in the way of experiments, repeatedly employed a mixture so strong, that its vapors eat the spores on fully developed patches as clean away, as would muriatic acid a spot of rust off iron, without the least deleterious effects upon young leaves and flowers, which were both represented on the plants under treatment. The vapor produced by a dilution of 25 per cent makes very short work of the spores, whilst the undeveloped spots rapidly change colour, turn brown, and die. With one vessel I used, common cups, I worked at a disadvantage, as carbolic acid only partly dissolves in water, the thick sheet of which, overlaying the stock of acid in the bottom, was obstructive to the rapid and steady production of gas. The vessel I have modelled for general use has with equal capacity nearly double the evaporating surface, and a simple and inexpensive contrivance in it will ensure a steady production of gas, and economise material in using up the greatest possible quantity of the acid present in the dilution by turning it into vapor. Nor need there be any fear of danger to the laborers handling the fluid, as a properly constructed feeder will obviate that and the chance of any waste.

With Mr. Ward's experiments with carbolic vapor and the conclusions he arrives at, I entirely disagree. If Mr. Ward had wished to deceive himself against his own better judgment he could not have improved thereon. By his own showing, the most important agent for the absorbence and conveyance of the vapor to the foliage and the fungus patches—atmospherical moisture—was absent. A sporepatch in the open air under the influence of the vapor changes its appearance several times. The older spores in the centre first begin to look yellowish and attain a dry, gritty kind of look; the younger spores nearer the edges turn brown; and after a day or two in the early morning with the dew on the leaves or on a showery day, it will be seen that the patches of spores, in good health, always dry and seemingly greasy and impervious to wet, are as wet as the rest of the leaf-surface, the surest sign of their death. I have seen the spores on new vigorous patches die, and with those following on below and the layer of dead ones, fairly form a dish of brownish paste, the thickness of the nib of a quill pen. The atmospherical moisture impregnated with the vapor is precipitated upon both sides of the leaves, thus working the destruction of mycelia and spores, and in dry time, when the foliage is dry, respiration of the leaves through their stomata continues the work. It will be seen from the above that the very conditions most favourable to the growth of the fungus, calm, dewy nights and close steamy days, are also those under which the vapor is most destructive.

So much for the action of carbolic vapour upon ripe spores and upon growing mycelia within the tissue of the leaves, supposed by Mr. Ward and other scientists to be *safely ensconced* against the ordinary enemies of their tribe, and this constitutes the one chief point upon which I am at issue with those gentlemen, much as I must admire the keenness of research and observation brought to bear upon the life-history of the fungus, and the valuable, because useful information resulting therefrom.

I have repeatedly seen scientists and other of your correspondents lay great stress upon the action of the wind in the distribution of the spores of *Hemileia*, etc., whilst it appears to me that the passage of labourers among the coffee, brushing off the spores from one tree and in the same manner again depositing them on others, is the chief means of dissemination. Here in Fiji, nearly, if not all cases of infection during the time of the first introduction of the pest were noticed by and reported to me as having occurred near a landing-place or immediately around men's huts, in every case plainly pointing to bodily contact; whilst infection through atmospherical means in a country were coffee plantations are for the most part so small and so far apart could only happen through the merest chance. With you in Ceylon the monthly system of weeding would sufficiently account for rapid contagion.

I was much pleased at Mr. W. Sabonadiere's letter and flattered at the notice he takes of my doings and writings. The Nestor of coffee planters recognizes the soundness of the principles upon which I have based my operations, and would go a good deal farther in the application of my treatment than I ever dared contemplate, even though I more than *once hinted* at the expediency of removing every possible source of reinfection outside of plantations under regular cultivation.

The gratuitous remarks of Mr. Schrottky upon my mode of treatment I could have overlooked, had he not committed the naivety of stating "that he would have been glad to borrow anything useful from me," when he had already borrowed that which constituted the chief feature of my process, and through which he hopes to change his own, a manual and direct treatment, and as such a failure on the face of it, into a neutral, permanent and successful one. Mr. Schrottky's doings lack every element of original conception and invention, nor will borrowed plumes avail him anything.

JACOB P. STORCK.

THE BRISBANE BOTANIC GARDENS.

From the Brisbane Botanic Gardens and from those of the Acclimatization Society the farmers and horticulturists of Queensland have been liberally supplied with plants suited to tropical and intertropical climates, to the great profit of individuals as well as to the advantage of the country. The Botanic Garden, judging from its last report, seems as flourishing and useful as ever. For instance, it is stated that :—

Several varieties of cinchona have been planted, and are doing well. There have also being planted several varieties ot Landolphia, valuable rubber plants discovered in West Africa by Dr. Kirk. Trial beds of Liberian coffee and Assam tea have also been formed. Two stools of each variety of sugar-cane in the collection at Oxley (forty- two in all) have also been planted in these beds, and have doen remarkably well.

And we have a reference to both species of coffee in the following extracts :—

It is also mentioned in this report that during the year many coffee planters from Ceylon have visited the gardens, and all have expressed their admiration of the productiveness of the coffee plant in Queensland, as shown by the group of specimens in these gar dens —the crop of berries being greatly in excess of anything they have seen in Ceylon for some years, owing to the ravages of the coffee-leaf disease. This disease being unknown in this colony, it is the unanimous opinion of these gentlemen that if cheap labour could be obtained coffee-growing would become a great and profitable industry ; as it is, many small farmers are turning their attention to coffee-growing, and find it more profitable than the exclusive cultivation of corn or potatoes, especially where there is a family of children to gather the berries. Several small quantities of green berries have been disposed of in Brisbane at from 8d to 10d per pound. Liberian coffee also promises to do well, at least in Northern Queensland, it being very successfully grown on the Herbert River by Mr. F. Neame, of Macnade, and Mr. H. A. Wickham, of Maragen. The demand for plants of this variety has been exceptionally great from all parts of the colony, and all applicants have been supplied from the plants in stock. In order to guard against the introduction of disease, it is intended not to introduce any more seed from Ceylon or Fiji, the seed of Liberian coffee kindly sent from the Herbert River being quite equal to the imported seed.

Upwards of 5,000 coffee plants have been distributed, including 1,000 *Coffiea Liberica*, of which there are now 2,000 plants in stock.

The demand for general economic plants has also been very great, especially from Northern Queensland, and among others the cinchona tree has been distributed. The resources of the establishment have been taxed to the utmost in the supply of tropical economics, and if this is to be maintained increased means of propagation will be required. During the year 15,000 plants and ninety collections of seed were distributed.

The curator acknowledges his indebtedness to the British-India Company for gratuitous carriage of plants and seeds to and from Europe.

In connection with the Oxley Forest Reserve, it is stated that when it became known that the sugar-cane growing on this reserve was to be distributed among intending planters, applications from all parts became very numerous, and during August and September, 40 tons in forty varieties were distributed to seventy applicants. As it was impossible to meet all demands, an additional two acres was planted, and this will probably be all required for distribution this season. Notwithstanding the drought the young cane has done exceedingly well, which may be attributed to the ground having been well cultivated before planting.

The forestry department has also been considerably extended. A quantity of plants of silky oak (*Grevillea robusta*), Moreton Bay chesnut (*Castanospermum Australe*), planes (*Platanus occidentalis*), poplars, willows, and mulberries of various kinds have been raised. There are now ready for distribution about 15,000 plants of red cedar (*Cedrela Australis*). It is much to be regretted that owners of suitable land do not plant this valuable timber tree more largely, especially when any number of plants would be supplied by the Government from this nursery.

That little word " if " is amongst the most important in the English language. *If* only the Queenslanders can obtain a supply of cheap labour and if they can only keep out the ubiquitous and deadly fungus, the coffee enterprize may be as great a success amongst them as sugar promises to be. But there are great difficulties about cheap labour, and we fear that, in ceasing to import seed from Ceylon and Fiji, our southern friends have but closed the stable door after the steed was stolen. If *Hemileia vastatrix* followed Ceylon coffee to Fiji we scarcely see how it is possible that it should not develop in Queensland. But whether it does or not coffee is not likely to be grown on a large scale until the labour wants of the sugar enterprize are met. The Agricultural editor of the *Queenslander* states :—

A correspondent writing from the North, and commenting favourably upon the article on "Coffee," which appeared in our pages a few weeks back, expresses surprize that we did not recommend leaving large trees standing here and there in the plantation. It is hardly possible for any one acquainted with the nature of our forest trees, and aware of the scant rainfall of the colony, to say one word in favour of such a practice. Established forest trees send their surface roots through every inch of space within 50 or 60 yards of their stem, and if they find a bit of worked ground will pounce upon it, to the injury of the tender plant; and even if weekly attentions were bestowed upon such worked plots the feeding roots of the old veterans could not be kept out of it. Besides, the coffee plant is not tender so far as sun is concerned ; it revels in our greatest heat, so long as it is well supplied with moisture ; water in good quantity, however, is a *sine qud non*, and for that reason large trees would be the bane or ruin of the coffee shrub. In climates such as Ceylon or Java, where the rainfall is mostly in excess of requirements, large trees may be of service in absorbing some of the superabundant moisture. The only things that have ever withered the coffee plant in Queensland, so far as can be ascertained, are frost and drought, either of which cut up the plants severely. To avoid the former, plant only well up on hill-sides ; and to escape drought, practice deep cultivation.

The position taken up respecting shade even in the dry climate of Queensland is, we believe, correct ; at any rate in the deprecation of leaving old forest trees in the ground. But it is a curious mistake to suppose that shade would be useful in Java and Ceylon because of superabundant rainfall. It is not because of the heavy rains at one season of the year, but because of the trying drought which too frequently follows, that shade is deemed necessary in Java, and even there the original forest is not left standing. Special shade trees, such as the dadap (a species of *erythrina*) are employed. The experiments tried in Ceylon have ended in the general conclusion that, where coffee cannot be grown without shade, it had better not be tried. Apart from the effects of the roots of old forest trees in robbing the coffee bushes

of nutriment, the dense shade and the drip are serious objections. In Southern India, however, shade is generally used, the favourite trees for the purpose being Indian figs. Many of these, including the noble Moreton Bay Fig, are native to Queensland, so that, if the coffee enterprize is really entered on extensively, experiments with trees likely to be most beneficial and least injurious as shade can be easily tried.

THE INDIARUBBER INDUSTRY IN BRAZIL AND CEYLON.

is the subject of discussion in the Rio Press. The *Rio News* writes :—

Concerning our comments on the new rubber-producing industry of Ceylon, and of the backward state of that industry on the Amazon, our esteemed contemporary, the *Diario do Gram-Pará*, contests both the accuracy of the observations of Mr. Henry Trimen of Ceylon, from whose report we made a full extract of the discussion on "coffee" and "rubber" and the deductions which we drew from them. We are inclined to believe that our colleague misunderstands the position assumed both in our extracts and and in our comments, as he devotes his whole attention to proving the comparative superiority of the Parà rubber, and of its inexhaustible supply on the Amazon. As far as we know, no one seeks, to under-rate the excellent qualities of Parà rubber, nor the immense supplies still within reach. What we sought to demonstrate was the energetic measures adopted in Ceylon and India to *cultivate* this product, and the apparent good chances of success. We then drew attention to the apathy existing in this country on this growing competition—just as it has existed in the case of coffee production—and of the wasteful process still employed in the industry on the Amazon. We also drew attention to the gradual recession into the interior of the rubber-producing localities, giving the receipts this last season from the Rio Beni as an instance. The *Diario* replies that the Beni is in Bolivian territory, and that the rubber came down in canoes until it reached the river steamship route, where it was shipped down the Amazon by steam. This, however, does not meet the argument. We held that the rubber industry in Brazil is still primitive and destructive, and that it is steadily receding into the interior, thus increasing the costs of production through increased inland transportation. We learned from one of our Pará or Amazonas contemporaries that the first shipment from the Rio Beni came down this last season to Manáos—and all the way by canoe. Whether gathered on Bolivian territory or not, it still proves the truth of our statement that the industry is receding into the interior. Furthermore, our colleague must admit that scores of rubber-producing localities on the lower Amazon are now entirely unproductive and deserted, and that even the villages of rubber-gatherers have gone up the river with the opening of new *seringães*. So true is this that travellers are often shown the sites of these abandoned villages, now over-grown with new forest. These facts prove the correctness of our argument, and should prove also the logical conclusion which we drew that the industry is in serious danger. It is all well enough to point out the excellence of Pará rubber, and its steadily increasing commercial importance. In this connection it should be remembered that the increasing export is due to the increasing uses of rubber throughout the industrial world, and that this means as much for other producing countries as for Pará. Whenever the cost of Pará rubber becomes too high in comparison with other grades, nothing is more certain than that manufacturers will make more minute classifications of grades for special uses, and will find a wider use for the inferior grades. If Brazil chooses to sleep until that time, she will then find that the child of today has grown into a strong man—that the new producers who are now planting, cultivating and experimenting, have won a position where they can compete on advantageous terms. Even admitting that Ceylon and India may never be able to produce a grade of rubber equal to that of Pará, the fact still remains that they will eventually conquer an important part of the consuming market and may restrict Pará to the supply of a special grade for special uses. As in the case of coffee, it may occur that production will outstrip consumption, in which event prices and profits must fall. In such case how is Pará prepared to meet the emergency? Her source of supply will be distant and diminishing. The cost of production and transportation will be high and increasing. And she will be totally unprepared to make economies. We beg our colleague to remember that nothing is ever lost by looking facts square in the face. The export at Pará has been increasing hand over hand, but that means also a corresponding destruction of the source of supply. It mens nothing more than that more people are engaged in the business, and that more rubber trees are compelled to pay tribute to the demands of trade. In a developed industry this would also mean a more extended cultivation, and a consequent addition to the permanent wealth of the country. In the Amazon rubber industry, however, it means nothing of the sort. The people are becoming no wealthier and no more civilized. The land is not tilled, no new permanent improvement, are being made, the country is really not a shilling richer than before. It is true that a few more traders will gain profits from the industry, and that the tax-gatherer will gain new revenue from the increased product, but of what real value is this to the country? No country ever yet taxed itself rich, and no country ever gained but a slight permanent advantage from the profits of its frontier traders. We do not doubt the natural advantages of the Amazon valley in this respect, but we do doubt the wisdom of continuing so important an industry in a primitive stage.

The writer then goes on to contrast the backward state of Brazil first visited by the Portuguese under Caldeira three years before the pilgrims landed at Plymouth Rock and the progress of New England. The settlements on the Amazon do little yet except to collect and export forest produce which constitute 14-15ths of the exports from Para for the half-year ended June last. Rubber shewed for $12,350,000, say £1,235,000 for the half-year. At the same rate for the 12 months, the value would be £2,470,000. Our readers will thus see the great importance of the trade which the Brazilians are exhausting.

HINTS ON TEA CULTURE AND MANUFACTURE.

Tea planters throughout all the various districts of India, Ceylon and Java are now straining every nerve to reduce the cost of production, whilst at the same time improving the quality, and hence the following practical suggestions, prepared by a London firm having the agency of a large number of Indian properties, deserve wider publicity then they have hitherto been accorded They are specially directed to the more perfect economical working of Indian tea gardens, but they are equally applicable to the case of Ceylon, Java and Johore :—

Some of the more important points to be kept steadily in view are—

1st.—*Plucking* the green leaves at an earlier stage of development—allowing at the commencement of the season a free growth of shoots for the formation of young wood. It does not necessarily follow that this would entail any material reduction in the amount of crop, and any partial loss in *quantity* would be

more than compensated for by the higher standard of *quality* and value attained, and by the healthier tone that would be imparted to the Loudon market by the general adoption of this principle. In like manner any partial or occasional reduction in the daily task for leaf gathering, rendered necessary by this system, would be fully covered by the greater money value of the day's work, whilst there would be a substantial relative economy in all the subsequent operations, inasmuch as a maund of green leaf giving tea worth an everage of 1s 6d per lb., costs quite as much in charcoal, manipulation, lead, boxes and freight, as one giving tea worth 2s per lb. Taking even the extreme case, then, of a reduction of one-fourth in the bulk of the crop, if accompanied by a corresponding improvement in the quality, there would be a positive saving of 25 per cent. in the items indicated, whilst the market would be less glutted, and the absorption of the inevitable increase of importation incident to extension of cultivation would take place under more regular and natural conditions.

There are no doubt times—such as when a sudden flush of leaf comes out simultaneously all over the gardens—when it would be difficult to carry out this system and at the same time gather all the leaves. If such cases cannot be adequately met by a partial gathering of the suitable leaves over the whole area, then there can be little doubt that, rather than go on gathering coarse large leaf to produce comparatively worthless and unsaleable teas, it would answer better to suffer a portion of the garden to run completely *banjie* for a time, and to turn back and gather the leaf, while in a suitable condition, on the earlier plucked portions. The ease with which a basket may be filled with overgrown leaf no doubt affords a strong inducement to the coolies to persevere in that direction, but this is a minor difficulty which no competent manager would admit himself unable to control. The manager has also to guard against a tendency on his own part to strive after *bulk* in his crop as being the most important consideration, and the test by which he is likely to be judged. The sooner this illusory principle is discarded, and *quantity*, without being lost sight of, made strictly subservient to *quality* and *profit*, the better it will be for all concerned.

2nd.—The subsequent treatment of the leaf in the teahouse—the *withering*, *rolling*, *fermentation*, *firing*, *sorting*, and *packing*—all demand careful attention and supervision, if the fruits of all the preceding labour and expenditure—just within our grasp so to speak—are not to be more or less sacrificed and lost. In *withering* it is necessary that there should be ample space, and in *rolling* that care should be taken to avoid putting too much leaf into the machine at one time, and not to carry the process into excess, thus injuriously affecting the strength of the liquor to obtain, what is of infinitely less value, a well-twisted and a good-looking leaf.

Important, however, as these operations are, there is less room for serious error in them than in the following one of *fermentation*, to hit the right degree of which requires more study and discrimination than are generally given to it; and failure at this point is, beyond doubt, one of the most prolific causes of *poor teas of weak liquor* It is no unusual thing to meet with two samples which, having as nearly as possible the same appearance in the dry state, show such a marked difference in the infusion as to make one worth from 3d to 6d per lb. more than the other—a difference generally traceable to an error in fermentation, though it may also occur in the firing—more frequently from insufficient than over firing—or from the tea being allowed to lie about and become more or less musty before packing.

While the two extremes of *over* and *under* fermentation have to be avoided, the general tendency is to err on the side of excess. This sometimes occurs from inability to recognize the true indications of sufficient fermentation; sometimes from a want of appreciation of the importance of the point, and allowing it to be treated in a haphazard routine fashion by the tea makers. One cause of over-fermentation may be found in the habit, prevailing in many tea-houses, of allowing the leaf to lie about in heaps too long before firing, waiting for space to be available on the dholes or trays, there being a tendency, more especially in factories where steam is employed for the purpose, to push on the rolling of the leaf without giving any consideration to the adequacy of the accommodation for firing it off while at the right stage of fermentation. Another fertile cause of over-fermentation, producing dull, weak, and sour teas, is want of care in seeing that the fires are kept brisk and bright, and that no more leaf is put on each *chalnee* or tray than can be quickly fired off. When a thick mass of leaf is put over a slow fire, fermentation of course goes on even more rapidly than before, stimulated by the gentle heat, and a dull sourish tea is the certain result. Rolled leaf is in a fit state for firing off just as the original green colour is turning to pink. The cutturn of the infused leaf should be a *bright salmon brown*.

The first *firing* has thus been incidentally dealt with; the *sorting*, being a mechanical process which may be modified from time to time to meet the requirements of the market, does not call for special remark in this paper, beyond pointing out the great importance of its being done as promptly as possible, to be followed by an equally prompt *final firing*, carried to the point when the tea gives off the well-known malty aroma, and *packing* in a warm state—a most essential condition—so as to preserve the full freshness and aroma of the teas. Delay in this, and allowing the teas to lie about exposed to the atmosphere, is next, if next, to error in fermentation,—a most common and potential cause of deterioration, and one which cannot be too watchfully guarded against. Whilst, then, the most strenous efforts should be made to have all the operations (from the time the leaf is gathered till it is packed as tea) following each other in their due order without needless delay, it may sometimes happen, from pressure of work and an inadequate labour force, that this cannot be accomplished unless at a greater sacrifice than would result from a temporary delay in sorting and packing. To meet such cases, each factory should be provided with a few zinc-lined bins for storing the made teas, or where these do not exist, bins may be easily and cheaply made of ekara and naga, mats or machans raised foom the floor a sufficient distance to allow of charcoal fires being kept constantly burning below them.

This being the test by which brokers and buyers in England are guided in the sale and purchase of teas, it is certainly no less essential that it should be systematically and carefully applied by the producers, in order to obtain an approach to certainty, or anything beyond empirical, haphazard results, in the standard of quality.

THE COTTON SEED OIL INDUSTRY.

Speaking of the new era of prosperity for the South, Commissioner Kenner, of Louisiana, of the United States Tariff Commission, said to a reporter lately:—

"I made the prediction five years ago, and the present state of the business justifies the prediction, that the manufacture of oil and other products from cottonseed would within twenty-five years bring from one fourth to one-third to the South of what our section then got from the staple itself. This would yield an increase in revenue of probably not less than $100,000,000. The business has entirely grown up

since the war, and it is only within the past ten years that it has attained any importance. There are now sixty-five or seventy mills in operation or being erected, and the progress and profits of the manufacture are already established. When the chief mill in New Orleans was established some ten years ago we paid but from $7 to $10 a ton for the seed. Last year we were obliged to pay from $16 to $19 a ton. At first we could get such a supply as we wanted along the watercourses, and the transportation cost but little. The demand has grown to such proportions that we must now go into the interior, and the difference in the cost of getting the seed to market makes the difference in the price to us.

"For every bale of cotton—400 pounds—there are 1,200 pounds of seed. The annual cotton crop amounts to about six million bales, which would yield, after reserving the necessary seed for planting next year, about two and a half million tons of cotttonseed. This seed, if manufactured into oil, oilcakes and other products, would be in value not less than $75,000,000, and probably $100,000,000. All of this seed before the war, with the exception of that used for planting, was thrown away. We now buy all that we can get. With increased facilities of transportation, permitting the planters to ship their seed to the mills, the entire crop will be utilized, because the profits of the manufacture, with the price at not more than $20 a ton delivered at the mill, will induce the expansion of the business until the whole crop will be used. There will be always a ready market. All that is now made is readily sold. There are four products of the seed—the oil itself, lint necessarily left on the seed in the process of ginning, the cake and the residuum left after clarifying the oil. The oil is used for table purposes and for cooking; the oil cake for feeding animals and for fertilizers; the residuum for soap stock. Out of one ton of seed we get thirty-six gallons of oil and about seven hundred pounds of cake, besides the lint and residuum. The total value of the manufactured product yields a very handsome profit. Our markets for the oil are Italy and the Mediterranean ports: for the cake, England and Germany. Of course, large quantities of both are also consumed in the United States. Good judges declare that where cottonseed oil is well made and clarified it is hard to tell the difference between it and the best olive oil. Both are vegetable products, and there can be nothing purer or more free from injurious effects upon the stomach than is cottonseed oil. I have no doubt that the time will come when it will be used with fully as much savor as the salad oil from Europe. It is now used by thousands who cannot detect the difference between it and olive oil. I look to its manufacture as one of the great factors of the future prosperity of the South."—*Oil and Paint Review.*

QUININE.—Dr. Tuckerman says:—"Quinine may be rendered tasteless by giving it with powdered slippery-elm bark. Take about 5 grains of the bark and mix with about half a table-spoonful of water, stirring till the mass is thoroughly mucilaginous; then mix in a dose of quinine, and give it to the patient, following it with a swallow of water. The bitter is barely perceptible.—*Medical Brief.*

VANILLA.—The new crop vanilla has not yet appeared in the market: we have therefore no quotations to give. We do not of course make any mention of a few small lots of which the preparation was not even completed. The gathering of the pods is going on slowly, the ripening being somewhat late this year in the elevated regions of the island, from which we now receive the greater part of our vanilla. Gradually as the gathering goes on, it becomes apparent that the falling of the pods has been more serious than was anticipated at the commencement. We cannot however prononnce with any certainty on the probable amount of our crop for 1882-83.

ENEMIES OF TEA.—"Planter," Balangoda sends us a small box containing one or two 'caterpillars,' which have been doing much damage by eating down his tea seedlings. The 'caterpillars,' we are sorry to see, are none else than the common destructive black grub, against which patience seems the only effectual remedy. They will disappear as suddenly as they come, and meanwhile the tea seedlings will in the majority of cases send up a fresh shoot. Kerosine ought to do good, but the bed might also be watered with lime and water, or soot and water, and the grubs picked up and killed as they come to the surface.

NAPHTHALINE has recently found a new and important use in medicine. It has been found that this hydrocarbon is an excellent antiseptic, which kills fungi and bacteria in a short time. For surgical bandages and in contagious diseases, so far as experiments have been made, it has answered an excellent purpose, and seems well adapted to replace in many cases those antisepties now so much used, namely, carbolic and salicylic acids, and iodoform. It has one great advantage over carbolic acid, being absolutely free from poison, and can, therefore, be used in any desired quantity without causing any disturbance It also surpasses all other antiseptics in cheapness. As 100 kilos of pure naphthaline can be bought for 60 marks (about 7 cents per pound), there is no doubt that it will soon find general use for medical purposes.—*Oil and Paint Review.*

CHINESE TEXTILE MANUFACTURES.—It may not be amiss to call the attention of the British cotton and silk trades to the fact that the Chinese are making arrangements for the manufacture of both textiles on their own account. Under this head in the reports recently issued by the American Consuls—one of whom, Consul Stevens, states that a cotton factory of the most perfect construction is shortly to be erected in Shanghai. Consul Bandinel writes from New Chiang to the effect that the local officials contemplate establishing a company in the very heart of the silk district. for the purpose of employing foreign machinery in the treatment of the raw article and in the production of silk piece goods. In view of this undertaking, the cottagers of the adjoining districts have been ordered to acquaint themselves with the most approved methods for rearing the worms, killing the cocoons, and reeling off the silk. It need scarcely be observed that if the Chinese seriously set to work to provide themselves with their own cotton and silk piece goods an unmistakeable blow will have been delivered at our Lancashire and Cheshire commercial centres.—London *Times.*

CASUARINA CULTIVATION AT MADRAS.—A Correspondent, writing from Madras, says:—"A great part of the road (between Ennore and Madras) is bordered by casuarina plantations, looking as neat and well kept as many coffee estates. The trees are planted in rows and carefully watered when necessary. Weeding is also attended to, so that the young plantations look very well. And all this upon poor sandy soil which used to be next door to waste land. It is on the coast, and I believe that the sea-breezes are said to have something to do with the success of casuarina cultivation here. Most of the plantations are owned by Europeans, but the natives have begun to open their eyes and see what benefits are to be derived from such an enterprize, so that I suppose there will be great demand for the many thousands of young plants now in nurseries. Ennore is a lovely spot, with a salt water lake at its back and the sea on the other side. Fine bathing and the lake is large enough for a good sail." Casuarina cultivation ought to do well on many parts of the east coast of Ceylon, but then there is no market there, and on the west coast the more valuable coconut palm is ubiquitous, while firewood is obtained along the line of railway to Kandy, from the *wā* (*cassia florida*) andother indigenous trees.

Correspondence.

To the Editor of the Ceylon Observer.

OIL OR EXTRACT OF EUCALYPTUS AND GUMS: USEFUL HINTS BY AN AUTHORITY.

DEAR SIR,—In reply to a planter's enquiry (page 384) as to how the oil or extract of the eucalyptus is prepared, I send you the following from Squire's "Companion to the British Pharmacopœia." :—"*Liquid extract* of eucalyptus rostrata.—gum 1 part, water 2 parts: dissolve and strain. An excellent remedy in arresting bleeding from the nose: to be injected into the nostril. Lint dipped in it checks bleeding from wounds. The gum is used in doses of 5 grains every 4 hours in diarrhœa and dysentery. The oil is obtained from the leaves by distillation."

Reading of the antiseptic properties of blue gum, and the question "can we not turn our gum trees in Ceylon into some use," reminds me that large quantities of cashew gum are not collected and used, owing to persons not knowing that it can be utilized as well as gum Arabic if dissolved in cinnamon water, which is an antiseptic and keeps the gum from fermenting and turning sour. It is not generally known that distilled cinnamon water, which can be bought fresh from the oil manufactories in Colombo, preserves animal matter also from decomposition. It can be used for preserving flesh meat and specimens of natural history without decomposition. Large specimens of fleshy matter after being immersed in spirits can be transferred to vessels containing cinnamon water. This reminds me also of the beneficial effects of the pure oil of cinnamon for curing lameness in horses. A couple of teaspoonfuls of the oil and equal parts of salad oil should be well rubbed in on the affected part which will be blistered slightly; after which there will be an oozing of watery humour. A little olive oil should now be applied, and the lameness will disappear if the remedy has been properly used. At this season, when horses are affected by strokes of "land-wind," it will be found invaluable; also when rubbed outside the windpipe for catarrh. A light oil, resembling that made from cloves, is prepared by natives from the leaves. What I have found useful is the pure heavy oil, which sinks in water, and is made from the bark of the cinnamon tree only. For human adults equal parts of cinnamon and olive oil make a good liniment for chronic rheumatism.

Yours faithfully,—MEDICUS.

NEILSON'S PROCESS FOR CURING DAMP HAY AND CORN.

Thatched House Club, St. James' Street, London, W.

SIR,—Reference is made in a letter in your overland issue of 27th July to Neilson's exhaust fan for rick drying. I have given this fan a most successful trial this summer, and, without being able to say what it may be capable of doing with cinchona bark, I may shortly explain the process with hay. In a damp and partially aired state, the hay is carted into a round or square stack, in the centre of which a flue is formed in the usual way. A 9-inch drain pipe, laid underneath the stack, serves to connect this flue with the exhaust fan outside. Thermometers placed in tubes, set in the stack during building, shew the temperature in the interior. In 24 hours the heat registered will rise to 160°, when it is necessary to set the fan in motion. If driven by hand, it will reduce the temperature to 120° in about 80 minutes. The process is repeated day by day until the stack is permanently cooled and cured. This usually takes a fortnight. Heat sufficient to engender steam is necessary in the stack before starting the fan. The damp is thus extracted in the form of steam, and cool air is drawn from the outside equally through the stack. Unless the hay is allowed to heat, it is impossible to cure it. In making hay by this process, sun is still necessary. The fan supplements the sun, but does not take its place.

Failures in its use have been numerous, but chiefly have arisen from attempting too much or from carelessness.

There are numerous patterns of fan. I have used one by Phillips of Newport, costing £12. It is of iron and gives about 1,200 revolutions a minute. Driven by steam or water 2,400 revolutions are obtainable.

I have given the subject considerable and careful attention during the last twelve months, and with perfect success. I shall be much pleased to give any information in my power, and hope the system may be of use to Ceylon. The cost being small makes it worth a trial. It would be easy to work the fan by usual estate water power, and, provided the current of air can be distributed evenly over the bark operated upon, mould should be, I think, prevented, and the drying much accelerated whenever the air outside is fairly free of moisture. Long cylinders made of reepers and ceiling cloth, wherein to place the bark, might answer the purpose. But practical trials will have to be made, before this can be ascertained.—Yours truly, CHARLES S. COX.

CULTIVATION OF RICE ON COFFEE ESTATES.

Kalutara, 7th September 1882.

DEAR SIR,—The very interesting letter from F. B., in your issue of the 5th instant, on "Tissamaharama and the rice-growing enterprize of Europeans" opens an important question for discussion and careful consideration.

In times of depression like the present any new outlet for European energy and safe investment for European capital with early and good returns will be eagerly welcomed by every one interested in the colony. The object of this missive is to direct attention to what might be done on many estates in the lower districts and to ask Mr. Benzie, of Donside, to give the public, through your columns the particulars and returns from his cultivated ravines, as he can write with some authority, having a considerable acreage under cultivation and being past the experimental stage.

There are at the present moment many old estates at medium elevations which are barely paying their way or being worked at a loss with a hope that in a few years new products will take the place of old, and cocoa, tea, cinchona, or Liberian coffee flourish, and pay, where coffee arabica has died out or gone back so much as to be worked at a loss.

On most of those estates large quantities of manure have been applied from time to time and want of drains has sent a considerable amount of it down to the flats or edges of ravines, which have consequently very valuable deposits, if available for rice cultivation.

That in many cases those flats or ravines could be cultivated in paddy to great advantage there can be no doubt, and, while the outlay would be very small, the returns in the shape of rice for the coolies would go a long way to keep the pot boiling till the better times (we have looked for so long) come round.

Ramasamy is a very long-suffering party when he gets his weekly allowance of rice; and an occasional rupee, but when the rice is stopped he "cuts up rough" very soon. The possibility of being able to grow rice for estate requirments (a very few bushels do nowadays in many cases!) and being inde-

pendent of the tribe of gentlemen who go about with massive gold rings and red umbrellas, and not unfrequently a bundle of summonses by way of amusement, and have the monopoly of the rice trade in their own hands is enough to send a gleam of hope to many a down-hearted and hard-up planter.—Yours truly,

B. F.

P. S.—I think Mr. Benzie told me his returns were from 50 to 70 bushels paddy per acre, as compared with 20 to 25 in good, lowcountry paddy fields.

B. F.

HYBRIDISM IN CINCHONA.

Hope Tea Estate, Ouchterlony Valley Nilgiris,

September 8th, 1882.

DEAR SIR,—Having read in the columns of your excellent periodical, the "Tropical Agriculturist," various articles and letters on the above important subject, I shall feel much obliged if you will permit me, even at this late period of the discussion, to add a few independent remarks in support of the hybrid theory.

I believe that no supposition is more generally entertained than the erroneous one that cinchona will not hybridize or cross-fertilize. This popular idea, however, is supported by very tottering evidence, and even after taking into due consideration the most salient points argued in favour of non-hybridism the fact must remain conclusive to any painstaking observer that hybridism and cross-fertilization prevails considerably and in some instances extensively among the various species of the genus cinchona. Any person who has studiously examined the many varying forms of trees on the Nedivuttum plantations must, I am certain, arrive at the same conclusion; but I think the most distinct results are to be seen among the more recent progeny of the Nedivuttum trees, many of which are now flourishing on the most important estates in the Wynaad and Ouchterlony valley, the marked difference not only being distinctly prominent as regards form, shape and structure of leaf, but the habits of the trees, the colour of the flower, forms of capsule, &c., differ in many instances most materially, and forms may be noticed gradating in every conceivable degree between all the commonly cultivated species. On the Hope estate I have noticed the "Pata" of Mr. Cross—Pubescens—and two more less distinct kinds springing up spontaneously among the many self-sown seedlings which originate from a few mature succirubra and officinalis; and in this instance I may mention there is not a seed-bearing tree of "Pata" or even Pubescens within several miles.

The arguments of some gentlemen extend over a very unlimited and indefinite range when they bring forward the case of wild plants and even mention animals in support of their views.

I for one fully believe that the range of hybridity among plants in a state of nature occurs but rarely. Under cultivation, however, circumstances are broadly different. Here we have a number of species of cinchona all having their natural reproductive organs fully developed, that have already been under cultivation several years, and yet we are told they will not hybridize or even cross-fertilize in any other way than that of artificial impregnation, and even any permanent benefit arising from this process has been more than doubted by several recognized authorities.

Many of our leading horticulturists at home are clever hybridists, and they are also perfectly aware that the species of many genera hybridize, under the influence of insect agency when growing in convenient proximity; but now we are asked to believe that cinchonas, even when seven or eight species are planted together indiscriminately without any regard to specific separation, will not take advantage of this very natural method of crossing.

Very few persons doubt the genuineness of our famous hybrid perpetual roses or cavils at the origin of the choice hybrid forms of primulas, calceolarias, begonias, orchids, &c. &c., and the many hundreds of choice fruits improved on from time to time; but if we are to credit the anti-hybrid enthusiasts all this must go for nought, leaving us no alternative but to passively accept the probability that all these fine hybrids must have existed contemporary with Noah's ark or the still more remote days of Methuselah.*

The only definite way in which to settle the controversy to the satisfaction of everybody concerned can only be attained by a series of carefully-conducted experiments with the inferior as well as the more desirable kinds, and, if one or more of the leading growers in each cinchona district, combined to undertake simultaneously a course of experiments and at the conclusion carefully compared results, there can be but little doubt that the supporters of non-hybridism in this genus would find themselves considerably enlightened, and I for one firmly believe it to be only a question of time, when by judicious crossing and selection, forms will be obtained equalling in value and exceeding in robustness our now famous Ledgeriana.—I am, sir, yours faithfully,

W. T. KEMP.

Ouchterlony Valley.

CALISAYA MORADA.

Udagama, September 8th, 1882.

DEAR SIR,—It may interest some of your readers, especially those who have any of the seed, to read the following extract from a letter just received:—Can you spare me me a little of the Morada cinchona seed? I saw a small packet which you had sent up here to ————. I am told the bark (*husk ?*) glistens with quinine."

To shew the care taken to procure the real thing, the following remark that I find in an old letter from South America may also be worth quoting. Referring to a proprietor who could, *if he liked*, supply the best, it concludes by saying "it is next to certain he would supply me *trash*."

Sometime ago I wrote to a friend to whom I had given a little that I believed it would turn out *cinchona "rex"*—an opinion I see no reason to alter—and I venture to write again about it, as the subject is one that must be of some importance to cinchona growers; for it amounts either to possessing the best kind in the world (for surely the Bolivians themselves should know it, if any one does? and that they regard C. Morada *as such* is certain), or, as Mr. Moens says in his letter to me, its *counterfeit*, and "trash," not only representing a complete waste of purchase money, but a waste of the ground it is planted on, and, as he adds: "'nothing but disappointment,' and a loss of profit at the end of, perhaps, five years.' It is either one thing or the other.—J. C. R.

P. S.—There are no more seeds of any kind for disposal, but, as application has also been made to me for "cuzco maize blanc," and particulars as to its "superior characteristics," I copy a few from Markham's book, in case you may think them of sufficient general interest to be worth publishing.

(*Extract from Markham.*)

The Cuzco maize, and the quinua of the lofty *punas* of the Andes are two cereals which are most valuable in their native land. Cuzco maize is one of the great results of Ynca agriculture, one lasting proof of the civilization of ancient Peru. Maize, as a cereal supplying millions of people with food, is one of the most useful gifts which the Old World received from the New. But

* According to the received chronology the death of Methuselah took place in the year of the Noachian deluge.—ED.

the maize of Cuzco surpasses all other kinds in its yield and in its excellence.

The earliest notice of this magnificent corn is from the Yuca Garcilasso de la Vega who was born at Cuzco and brought up upon the Cuzco maize, and who published his account of it in 1609. He says that what the Mexicans and people of the Antilles call *maiz*, the Peruvians call *sara*. He adds that there are two kinds of *sara*. One is hard and the other is tender and highly esteemed. The Peruvians made different kinds of bread and cake from the maize. The sacrificial bread called *canca*, the festive bread *huminata*, ordinary bread *thanta*. They also made fritters called *api*, boiled puddings called *muti*, toasted grains called *camcha*, and cakes. They made a fermented liquor from the flour called *acca*, and a strong spirit called *sora* and *vinapu*, as well as vinegar. A good sugar was obtained from the stalk. The stalks and leaves were used as food for cattle, whilst the leaves of the cobs were in request for rubbing and smoothing stones for sculptors. The Yuca Garcilasso tells us that he saw all this with his own eyes, and was sustained and nourished on this *sara* until his nineteenth year.

The Jesuit Acosta, who was in Peru from 1570 to 1586, speaks in admiration of Peruvian maize. He says it grows on stalks, each one producing one or two cobs, and that on some of the cobs he counted 700 grains. It must be planted by the hand, one by one, and not very close together, and it is not uncommon to gather 300 bushels for 1 bushel sown, whilst the green leaves and stalks are used for food for cattle and mules.

The Cuzco maize is so called from being cultivated in the warm valleys in the neighbourhood of the ancient capital of the Yucas, but two to three thousand feet below the site of the old city. Its grand proportions are due to the careful agriculture of the Yucas during many centuries. The stalk grows to a height of 15 feet, and the grains are four or five times the size of ordinary maize. The grains were white, red and yellow, yellow, red, and purple, and there were double cobs of immense size which were looked upon as sacred.

The year of the Yucas was regulated with reference to the maize cultivation. In June the people were occupied with the irrigation channels. Then came the sowing, the ripening, and the harvesting, each with its solemn festival. In the month of *Ayrihuay* (April) they reaped and harvested the crops, singing a chant called *yaravi*; and the Yuca himself with his nobles assisted in reaping the crop on the *Colcampata*, beneath the fortress of Cuzco. These wise sovereigns held the science of agriculture in high honour.

Cuzco maize was, and still is, cultivated in its greatest glory in the lovely valley of Yucay. It should be grown at heights from 8,000 to 3,000 feet above sea-level.

Here the Yucas constructed those marvellous hanging gardens which bear testimony to the skill and taste of the designers and where the Cuzco maize was gradually brought to perfection. The terraces are wider at the edges of the level ground, and, as they ascend the mountain sides, they become narrower until the topmost terrace, some 1,000 feet above the valley, is scarcely two feet broad. The terrace walls are of rough stones, slightly inclined inwards, and varying in height according to the slope of the mountain, from 3 to 15 feet. An artificial aqueduct, starting from the verge of the snow, is conducted through the *andenes*, whence the water is led along each terrace. The terraces were filled with rich soil from which every stone was removed; and here grew the noblest of all the varieties of Cuzco maize, the *yura-sara* or white maize (*Maiz Blanc*) of Yucay. The palace of the Yucas high up on one of the loftier terraces was surrounded by the glorious maize of Yucay, and had a view from its halls quite unequalled for combined loveliness and grandeur.

In a subsequent report Colonel Chamberlain said that the Cuzco maize was incomparably the finest variety he had ever seen, and that for table purposes there was nothing known to him equal to it. He adds that it could be used as a most excellent and nutritious food for cattle.

The next year Colonel Chamberlain sowed a quarter of an acre with 400 seeds which produced 38,000 grains in magnificent cobs and 680 lb. of green stems. He pressed out 640 lb. of stems in a sugar mill and boiled the juice which gave 15 *sirs* of raw sugar or 4 lb. of refined sugar and four bottles of spirits. This sugar was of good market value for refining, worth 8s to 14s per cwt. If the proper methods had been used from 10 to 15 lb. of refined sugar, instead of 4 lb., would have been obtained, which is a third of the quantity produced from sugarcane. But the sugar is an *extra* product.

GRAFTING LEDGERIANAS ON SUCCIRUBRAS: IMPROVED METHODS.

[The following very interesting letter deserves and will receive the best attention of cinchona planters. —ED.]

Ouchterlony Valley, India, September 12th, 1882.

DEAR SIR,—The following remarks regarding grafting *C. Ledgeriana* upon *Succirubra* may prove of interest, if not of benefit, to some of your numerous readers in Ceylon, at present engaged in propagating this valuable variety. I have seen several methods described from time to time, but, as the following are original, as practised by myself, I now embrace the opportunity of placing them at your disposal.

In the first instance, the stocks suitable for grafting are prepared as follows :—Select the requisite number of plants, the size and age of which must correspond as nearly as possible with that of the graft, and, after trimming the roots liberally back, head them down to within 6 or 8 inches of the collar, and plant them temporarily in a shaded bed of light soil until fresh young rootlets commence pushing, when the plants will be ready for the grafting operation.

My grafting is performed by stumping the stock finally to within 2 or 3 inches of the collar, then with a sharp knife make a clean cut upwards entirely through the plant, leaving a clean, sloping surface about 1 in. or 1½ in. in length, terminating if practicable with a bud. Then take the graft, and, after making a cut of a corresponding and similar length downwards, place the cambium lips at once together, binding the whole gently but firmly with any good tying material available.

I find a vegetable fibre which decays in a short time when subjected to atmospheric moisture preferable, as it obviates the necessity of loosening the ligature after the graft has united with the stock; and, bearing this well in mind, I have used the fine fibre of the Neilgherry nettle (*Urtica heterophylla* Rox.) with signal success. The operation is completed by claying the grafted part, for which purpose an excellent composition can be prepared by taking a quantity of the well-worked clay from the haunts of those busy creatures, the white ants, and kneading it thoroughly with one-fourth of its bulk of freshest cow manure. Plant out in a well-prepared bed, burying the collar and greater part of the clayed part below the surface, and for protection adopt either bamboo cylinders or glass bottles.

If above the region of white ants bamboo cylinders are the best and cheapest and prevent chills. These are easily prepared by sawing them to the required length and placing one over each graft sheltering at the top with a broad leaf or any substance through which a little light can penetrate.

At the elevation where white ants abound bamboos are practically useless; so the grafts are sheltered by bottomless bottles which are in every respect as efficacious as the more expensive bell-glasses. The bottles are prepared for the special purpose by the following system. Having collected a sufficient number of bottles (no easy matter sometimes), pour in each a sufficient quantity of cocoanut or other vegetable oil enough to cover the bottom; heat the oil quickly by immersing the red hot end of an iron bar, and after withdrawing the bar place the bottle a few inches in cold water. This at once causes the bottom to crack off, leaving the necessary part intact, which can be inverted over the graft when required. After a bed is carefully planted, a thick, substantial screen or paudal should at once be erected, not only to shade the plants from sun during the day but also as a protection against the deposits of dew and moisture at night, which condensing inside the bottles would cause a large proportion of grafts to rot, should such a precaution be neglected or considered unnecessary.

No. 2—is a system performed in a somewhat similar manner, the chief difference being that the mode of attaching the graft to the stock is identical with that practised by Mr. Moens, of Java.

No. 3—suggested itself to me on observing aerial roots emanating from the point of junction in several instances on grafted plants and for simplicity of conception and general utility is I am convinced one of the most expeditious methods of propagating C. Ledgeriana as a cutting.

Take a piece of the stem of a young succirubra plant or sucker with at least two joints, the age and

texture of which must correspond exactly to that of the cutting, and, after splicing and claying in the manner described for grafting, plant firmly in sandy soil, taking the precaution to bring the clayed portion below the surface. The rooting process is greatly facilitated by placing a piece of brick or broken chatty at the base, so that the succirubra end rests upon it. In 5 to 8 weeks most of the cuttings should be wellrooted, and may then be lifted gently and transplanted into a well-prepared and shaded nursery bed. The above system can of course only be adopted during moist or monsoon weather, but success can be attained all the year round by practising in a suitable propagating house. I will describe another method before concluding, which can be carried out with great success in a propagating house or frame.

Prepare the grafts, as recommended at the commencement, and plant firmly up to the collar in a bed of fairly good soil under a propagating frame, and give the whole a gentle watering. Have ready a quantity of finely, sifted, clean brickdust, with which fill up to the point just above the clayed part. This precaution will effectually prevent withering, and keep the grafts plump and cool until they are established, and a gentle sprinkle with a syringe morning and evening on bright days will greatly assist in conserving the necessary amount of atmospheric moisture. For the first few weeks, shading will be necessary , and ventilation should be given judiciously, when the temperature exceeds 70°—Fahrenheit.—I am, sir, yours faithfully, W. T. KEMP.

CINCHONA AND COTTON SEED FROM AMERICA.

Sept. 13th, 1882.

DEAR SIR,—Mr. Millie's interesting letter in a recent issue of the *Observer* I think calls for a few words of assurance from me to the purchasers of the calisaya morada seed recently sold by Mr. Symons on my account. There can be little doubt that all Mr. Millie says is true, and that it applies with equal truth to Bolivia, from whence the morada seed came, as to Peru, the moral being that from seed collectors and official sources it is almost hopeless to expect genuine seed ; for, whereas the former, if too well acquainted with the best kind to be misled, may expect forcible obstruction, the latter will as certainly have their requisitions liberally satisfied with spurious supplies. That this is so, I have further proof in a letter lately to hand from Mr. Moens, referring to the manner in which their Consul had been imposed on :—"From our Consul, Mr. Schuhkraft, we got large consignments of calisaya seed, which proved after several years to be really 'trash,' though the seed was guaranteed pure, and of the best C. morada, vera, Boliviana, &c. In his last letter he warned me not to buy any seed sold in Bolivia, as all the growers try to sell the worst stuff they can get." And it is curious that my reply—referring not only to officials, but, strangely enough, suggesting the difficulties named in the way of seed collectors—should now unwittingly receive exact confirmation from Mr. Millie. That it all points to great difficulties in the way of getting reliable seed, there can be no question. But it cannot be said to *debar the possibility* of procuring the best kinds, especially if in small quantity, privately from the large landowners there who are now cultivating extensively, and particularly as in the present instance, if the seed be supplied as a personal favour. Apart from the fact that my brother, from long residence in the country, is likely to know who to trust and who not, that it came in husk (though disappointing enough to me financially, the seed when cleaned counting by ounces instead of pounds) goes, I think, far to support the assumption that the seed he has sent is genuine, and as stated "A 1." The small size of the capsules and seed, I also think, may tend to support the firm confidence I continue to have in its merit, though unaware that this can be justly considered a set rule. Specimens have gone to Mr. Moens, and go to Dr. Trimen, for their opinions, and I shall be happy to send a little to other local experts who care to do so, to examine. I am further endeavouring to procure the fullest information regarding it from South America, and also analysis or samples of the bark, in order that the quality of the variety may be more positively determined, for I think I may fairly add that I feel as keenly anxious to know the introduction a success, as others at present possessing it can.

Whilst writing, and as, though no more is for sale, it is being distributed, and has already, what has been sown (as also the maize blanc), germinated freely, it may be well to mention the Peruvian cotton again, as it seems to have attracted no notice, and I fancy this may be due to an impression that it is a plant similar to the ordinary American or Brazilian cotton, both annuals requiring a moist climate, and a failure here, I fancy, so far where tried. The Peruvian cotton on the contrary is a perennial, thriving in a very dry hot climate. According to Markham, it is in such a climate an enormously profitable cultivation, and I think it will repay any of your readers interested in the hot and dry districts of the low-country to look up the very interesting account he gives of it. J. C. R.

(Extract from Markham.)

"The Peruvian cotton tree grows to 15 feet in height with a branch 6 inches in diameter. It would probably live 20 years. But it is usually cultivated as a shrub to be within easy reach of the pickers. It sends down a very long tap-root, and the lateral roots are usually few and short. The Pinra cotton *(Algodon de Pinra)* is a shrub generally considered to require from nine to ten months to mature its first crop. Afterwards it produces every six months. When two or three years old, good plants have yielded in one crop 8 to 12 lb. of cotton, and even 18 lb. About 130 bolls give 1 lb. of cotton. The plants usually stand about 15 feet apart, and in 3 years begin to interlock. From 5th year the yield degenerates in quality and quantity, and at the 6th or 7th year the bushes are stubbed up and the ground resown. Taking the plants at 15 feet apart, there are 193 to an acre, yielding 1,544 to 2,316 lb. The Payta cotton is very white and soft with good length of staple. Yca cotton has the habit of Pinra cotton, and can be scarcely distinguished from it, but it produces the largest pods with the most numerous seeds, and consequently the greatest quantity of cotton. The respective lengths of the staples of the different kinds of cotton compared with Peruvian are as follows :—

	Minimum inches.	*Maximum inches.*	*Yearly inches.*
Sea Island	1·41	1·80	1·61
Egyptian..	1·30	1·52	1·41
Peruvian	1·10	1·50	1·30
Brazilian	1·03	1·31	1·17
New Orleans	0·88	1·16	1·02
New Orleans grown in India	0·95	1·21	1·08
Indigenous Indian ..	0·77	1·02	0·89

N.B.—1,544 lb. per acre per crop is equal to 3,088 lb., or at 25 cents R772 per acre annually.*

* But do the figures represent *clean* cotton, or cotton with the seed still in it ? Markham seems to indicate clean cotton, but the yield seems incredible.—ED.

A COFFEE SYNDICATE?

Trevandrum, Travancore, Sept. 19th, 1882.

SIR,—In your issue of the overland *Ceylon Observer* of the 2nd Sept., I notice a reference to a resolution passed at our late general meeting on the subject of a Coffee Syndicate, and I therefore take the liberty of offering a few words in explanation.

First of all, however, let me disclaim any intention on the part of our Association of starting the Syndicate ourselves. The Ceylon Association, being by far the largest and most influential body of all those interested in coffee, should take the initiative, if it cares to do so: we merely offer the suggestion, whatever it is worth.

It is, think, I generally agreed that the adulteration of coffee in England has increased to such an extent that, unless some very decided steps are taken for its prevention, it will not be worth while continuing to grow coffee at all.

The first thing that suggests itself is to frame a very strong and united remonstrance to the English Government against:—

1st. The adulteration of coffee with any other substance whatever.

2nd. The use of the name of coffee for substances which are intended to imitate or replace it.

For there is a great injustice done in even borrowing the name. Every one knows that coffee is a great preventative of fever, that it is the most invigorating drink after a hard day's work, and that it has many other properties that I need not detail here. When then people fail to find in the adulterated coffee they buy all the benefits they expect from it, they not only condemn the substance they have been drinking but consider that its valuable properties have been overestimated.

But it is necessary to go a step farther, or it may be many years before the British public will appreciate the value of pure coffee; so much is it accustomed to adulteration. When in England a few years ago I met an old schoolfellow who assured me that, though he went to the trouble of getting his coffee pure, he always bought chicory to mix with it, as he found it too strong alone. No amount of legislation could prevent this. A person who was accustomed to the use of sanded sugar or watered milk would probably find the purer articles hardly to his taste on first trying them, but, if it was properly put to him that he was loading his stomach with substances which, if they did him no harm, could do him no good, he would probably give the purer article a trial. For, be it observed, the most that is claimed for these adulterants is that they are harmless.

It is our duty then to give the British public an opportunity of comparing the two, the pure article and the adulterated. Now the best way of doing this, and one which seems also to have suggested itself to the Brazil planters, is to form a Syndicate in London to advertize, distribute samples, and extend the knowledge of Ceylon and East Indian coffees through Great Britain in every way. To turn for an instant to a parallel case. The Tea Syndicate of Calcutta was formed at the suggestion of the Indian Government at the time of the Melbourne Exhibition, to introduce Indian teas into Australia. Twenty thousand rupees were raised by subscription, and ten thousand more were given by Government towards the expenses, and a further sum of six thousand rupees was added by them when the Syndicate decided upon trying to open a market in America. Though it has been such a short time in existence, we all know how successful the attempt has been. It may be objected that this is scarcely a similar case, because our coffee is already retailed in England but is it really so? Is it not notoriously difficult to get pure coffee at the grocers' shops: indeed, but for the prevalence of adulteration, date coffee and other abominations would never have obtained a footing at all; so unlike are they to the real article.

This, sir, is our suggestion, and I trust it may commend itself to some of your leading men. As things stand at present, and while the grocer has the power to adulterate indefinitely, it is evident that the English market is controlled by him and not, as it should be, by supply and demand; nor can we ever hope to be compensated for short crops by increased prices, so long as he retains this power. And if all the capital expended, all our labour and all the discomforts we undergo have but one result, and that to swell the profits of those who risk nothing, the sooner we cease to grow coffee the better.—I remain, sir, yours faithfully,

T. F. BOURDILLON.

Secretary, Travancore Planters' Association.

SHOEFLOWER.

DEAR SIR,—I believe some time ago there was a talk about the shoeflower as an article of diet, especially to European and foreign palates unaccustomed to our fiery "curries." The ordinary four-petal flower * is an article of food as good as its manifold congener—a flower that measures, when fully developed, four inches in diameter and has five distinct blossoms embodied in one; but the quantity required to meet the requirement is very large. Of the latter, nine or a dozen will make a dish, the preparation of which is very simple. Pick the petals, say of a dozen flowers, wash and add 9 s. diluted salt and 6 billings or any other vegetable (except lime juice, which, by a singular chemical non-affinity, injures the mess and makes it tasteless) and a few sliced onions. When over the fire mash the contents into a paste and add 9 s. of the thick first extraction of coconut milk, boil it to perfection and you will find it "a dainty dish to set before a a king." A few leaves of spinach added will give the mess a delightful flavour. That the shoe-flower is a powerful anti-scorbutic and blood purifier I found out by experiment. A scrofulous lad placed by me on a strict diet that consisted of shoeflower curry, rice and gingelly oil, got over his troubles within one month; his skin is clear, and the fellow is as round as a pumpkin. I cultivate the plant largely for the flowers, which I eat freely, and give my children; and I strongly advise your readers to do the same, particularly those whose palates are averse to hot curries.—Yours truly,

COOK.

[The shoeflower (Hibiscus Rosa sinensis) so called because its petals are used for blacking shoes, is used by native cooks universally to give a rose color to all kinds of stewed fruits, auch as mango, pineapple, plantain, &c. It is mucilaginous and harmless like all the members of the family to which it belongs—the *Malvaceæ*. We quote the following account of the shoeflower from "Drury's Plants of India":—"In China they make these handsome flowers into garlands and festoons on all occasions of festivity, and even in their sepulchral rites. The petals of the flowers are used for blacking shoes, and the women also employ them to colour their hair and eyebrows black. They are also eaten by the natives as pickles. The leaves are considered in Cochin China as emollient and slightly aperient. The flowers are used to tinge spirituous liquors and the petals when rubbed on paper communicate a bluish purple tint which forms an excellent substitute for litmus paper as a chemical test. Rheede says that the root triturated with oil is useful in menorrhagia, and that the tender leaves rubbed with butter are applied to boils to bring them to maturity. The leaves are prescribed by the natives in smallpox, but are said to check the eruption too much." *Rheede, Don, Ainslie.*]

* Always *fine* petals.

SUGAR-MAKING IN, AND THE INTRODUCTION OF NEW VARIETIES OF SUGAR CANE TO, CEYLON ; &c.

Colombo, 21st September 1882.

DEAR SIR,—Referring to passages on the above subjects in the address of His Excellency Sir James Longden to the Legislative Council yesterday, I beg to offer a few facts which may not be generally known, and which may be of use to Dr. Trimen in case he attempts to introduce varieties of sugarcane to Ceylon:—It is likely that the real sugarcane (*Saccarum officinarum*) was introduced by the Portuguese or the Dutch to Ceylon, but in Moon's time, 1824 the white and purple stemmed varieties were grown in Ceylon.

The experiments made at Peradeniya, Paradua, Delpatgedera, Katukende and elsewhere to grow cane and manufacture sugar are all well known to have ended in failure, though some of them were conducted by old and experienced West Indian and Mauritius sugar planters.

When surveying in the vicinity of Katukende in 1841-2 I had frequent opportunities of meeting the Messrs. de Chermont, who had come to Ceylon from Mauritius on purpose to grow sugarcane and manufacture sugar, and from the felling of the primœval forest to the planting and reaping of the canes I watched the several operations with great interest. The Messrs. de Chermont imported all the canes for planting, I believe, direct from Mauritius, and I well recollect seeing the effects of the borer, the grub of a moth imported with the canes from Mauritius; nevertheless I have often said since that I never saw any plant that could compete with the sugarcane planted at Katukende for such a luxuriant and equal weight of crop. In from nine to ten months' time I should think the plants were from six to eight feet in height, and I do not believe that any thing that can be planted in Ceylon can produce an equal weight of crop in the same time as sugarcane.

I can scarcely doubt but the best varieties of cane then growing in Mauritius were introduced to Ceylon on this and subsequent occasions, and that it is not likely the natives lost the chance of growing all these in their gardens.

If His Excellency the Governor or any resident in Colombo will drive out between the hours of 7 to 10 a. m. by any of the roads entering the town from the direction of Kotte, Kaduwella, and the Bridge of Boats, they will find bundles of sugarcane to be the most abundant produce brought in to be sold to the inhabitants Women, children, and bullock-carts will be met with for several hours of the day carrying in loads to the extent of several tons' weight, all of which is grown within a distance of six to ten miles of Colombo in small private fields.*

A few days ago a small field of sugarcane was in full flower a little beyond the level crossing close to the canal at the new siding near Urugoddewatta, worth looking at by those who would like to see the sugarcane in full flower. Knowing of the success of the experiments carried on, on a small scale by the Messrs. Winter and Bowman at Galle, I suggested to a gentleman in Colombo the propriety of erecting a sugar manufactory in the vicinity of the great extent of cane-fields near Colombo, and buying the canes from the native growers. The reply was that the machinery required to manufacture our Ceylon canes into good sugar would be so expensive that it would not pay. I have no doubt that any variety, of the sugar-cane introduced by Dr. Trimen, and planted in a portion of the Heneratgodde gardens, would grow well, but, before any expense is incurred in this respect, Dr. Trimen should receive specimens of all the different kinds of cane now grown in Ceylon, and a report on the reasons for the failure of former attempts to manufacture sugar profitably in the island,

It is well known that several attempts made to raise large seeded varieties of the Indian corn, an allied plant, in the island, ended in failure. They all after a time degenerate into the most common small seeded form ; and I fear our soil cannot compete with that of Jamaica and Maritius for the growth of sugar-cane.

In respect to the conservancy of our forests, I think the reproduction of a discussion on this subject by the late Sir Coomara Swamy in the Legislative Council in October and November 1867, and a letter by myself would prove of interest now especially if a report of the result of the appointment of Government Conservators were appended,—Yours truly,

W. FERGUSON.

* Who can tell us the average yield per acre of such cane and its wholesale and retail price per cwt. or lb.? Five cents each piece or stalk is the quotation given to us.—ED.

CUPREA BARK.—Professor G. Planchon, in the *Journal de Pharmacie*, this month, throws some fresh light on the source of cuprea bark. A microscopical examination of the specimens supplied to him by M. Triana showed that the barks derived from Bucaramanga, in the north, and from Llanos, the southern district, both present the same characters and are evidently both furnished by *Remijia pedunculata*. The cinchonamine bark of M. Arnaud presents different microscopical characters, and is referred by M. Planchon to *R. Purdieana*. He remarks that a microscopical examination has never yet deceived him in the solution of like problems. A singular confirmation of the value of this method of research occurs in the form of a postscript to M. Planchon's article, in whichhe state that since it was written M. Triana has receive infromation to the effect that the cinchonamine bark does not come direct from Bucaramanga, but only passes through it, being collected near Antioquia on the other side of the Magdalena river. Further, that a large exporter of the cuprea bark has recognized the southern bark as the produce *R. pedunculata.—Pharmaceutical Journal.*

OSTRICH FARMING —In a young country it is always cheering to hear of the establishment of new industries particularly when it is done without the aid of any artificial stimulus, such as protective duties or a large State bonus. We therefore, hail with especial pleasure Mr. W. Malcolm's successful effort at ostrich farming at Buchsfelde, near Gawler. A year or so ago he paid a visit to South Africa, and noticing the large profits that were made by people who kept ostriches, he determined to purchase two or three birds and see how they would do in South Australia. He experienced some difficulty in keeping them alive on the voyage from the Cape, and lost one or two valuable birds, but nothing discouraged, he persevered until he had a number safely housed at his farm. Though little more than a year has elapsed since he started his operations, his enterprize has met with an excellent reward already. He has now a flock of 30 birds, of which only nine have been imported ; and he has proved to his satisfaction that the feathers of locally-bred ostriches are of equal value to those produced elsewhere. It is now clear that the climate and other conditions of the colony are suited for ostrich-growing, and there is no reason why the industry should not extend beyond the limits of one farm, as the demand for ostrich feathers is said to be practically limitless. We understand that the Government are disposed to favourably regard Mr. D. C. F. Moodie's application for a lease of 6,000 acres in the Far North, with which, assisted by a few of our leading colonists, he purposes establishing an ostrich farm. Should the experiment succeed, we shall have proof that an extensive area of the colony is adapted for what is to us a new, and probably may prove to be an important industry.—*Adelaide Observer.*

COFFEE AND RUBBER IN MEXICO.—This mail brings us an enquiry for information respecting coffee and rubber planting from Agua Zarca, Mexico, where the "Colima Coffee Company, organized under the laws of the State of New York," has its headquarters.

THE HOP BLIGHT.—A correspondent, formerly resident in Ceylon, who is recognized as an authority upon high cultivation, writes as follows:—"I have just returned from Worcestershire, where I have been visiting some of the hop 'yards.' The majority have suffered most severely from blight this season, some of the best managed and best manured equally with those of inferior quality. I have seen several acres temporarily abandoned for remainder of season, the weeds being allowed to grow up to any extent. Here and there we came on some good 'yards,' and others that have recovered, and in the latter the farmers are applying readily available manures to help the maturing of crop. This is what coffee planters might do when they get a good blossom and all set."—*Planters' Gazette.*

"FORESTS" OF CINCHONAS IN ECUADOR?—A consular report quoted by the *British Trade Journal* stated:—"Commercial prospects in Ecuador are not encouraging. Three out of four of the principal articles of export, viz., cocoa, ivory-nuts, and Peruvian bark, show a large decline in exportation, while the export of the fourth—indiarubber—has increased. Up to the present, however, no measures have been taken by the Government to prevent the cutting down of the trees producing this article, and the resources of the country in this respect are being gradually destroyed. As regards the supply of Peruvian bark, it is satisfactory to know that large forests of the best quality of bark-trees have recently been discovered in the interior. The low price prevailing in Europe has curtailed the exportation of this article, but supplies are ample. As is the case in Costa Rica, great things are expected from the development of the mining industry."

TEA CULTIVATION IN AMERICA.—The Americans are not yet convinced that their climate will not do for tea cultivation, and are now and again enlivening us with short paragraphs regarding the growth of their experimental plants. The latest information we have come across is the following:—"Tea culture in South Carolina bids fair to become an important industry. A reporter of the Georgetown *Enquirer* says:—'The tea plants of Friendfield Plantation, the residence of Dr. Forster's family, have been submitted for inspection to a leading importing house in Baltimore, and the tea produced therefrom is pronounced by them to be equal, if not superior, in pungency, and in strength and richness of flavour, to the finest imported article." It would be strange if the flavour were not good, but this is not the point. No man in his senses doubts that tea will grow in America, for the matter of that it would grow in Great Britain, but the point to be considered is, will it produce sufficient leaf to make its cultivation and manufacture profitable. Now, the climate of the Southern States, Louisiana, Mississippi, Alabama, Florida, Georgia, and South Carolina is admirably adapted for the growth of the plant. There rice grows, and there also, flourish other tropical plants as sugarcane, sorghum, and tobacco. Where these come to fruition, tea should grow. Thus it appears, have the Americans argued, but while the plant will grow, to make it pay, it is necessary that the growth of leaf should be very great, and heat alone will not effect this, a rainfall being also required. The rainfall of those States does not exceed 29 inches per annum, and with such a mild climate as is developed in those States, by the proximity of the Gulf Stream, 29 inches of rain are utterly insufficient to enable the bushes to flush profitably. There are many crops which can be cultivated to perfection in that great country, but tea is not one of them,—*Indigo Planters' Gazette.*

A NEW OIL FACTORY.—Messrs. Parry and Co., Madras, are now constructing a factory at Bandepalleum, for the purpose of manufacturing oils of different kinds. The works are pushed on vigorously.—*Madras Mail.*

SUGAR FROM TODDY.—The success of Dr. J. N. Fonseca, author of the History of Goa, in converting toddy of the coconut tree into chrystallized sugar, has been hailed with satisfaction by the press at Goa, and flattering calculations are made of the advantages that will accrue to the country from the development of this new industry.—*Bombay Gazette.*

COMBINATION OF QUININE MAKERS.—An announcement has been published that the houses of C. F. Böhringer & Sons, of Mannheim, Böhrioger and Geyer, of Stuttgart, and the Fabbrica Lombarda di Prodotti Clinnica, of Milan, have amalgamated their businesses. Arrangements have been long pending, and, in consequence of the recent sudden decease of Mr. C. H. Böhringer, of Mannheim, have been concluded. Mr. B. Kühn, who has been the London representative of the Milan house, will henceforth represent the combined firms.—*Chemist and Druggist.*

RUBBER.—In the annual report of the Forest Board of South Australia for 1880-81, there is much from which we in India might learn. Perhaps the most instructive item in the report—at least to us, is the fact that the department confined itself very largely to the propagation of indigenous varieties of trees. In India we have a hankering after exotics, and even where we have a superior indigenous variety, we spend years and large sums of money over efforts—often fruitless—to introduce exotic varieties. The India-rubber tree is an example of this. We have the *Ficus elastica* which flourishes and grows well, but our experimenters prefer making expensive efforts to introduce the *Ceara* and the *Hevea* from South America.—*Friend of India and Statesman.*

FOR CINCHONA PLANTERS: ESTIMATION OF ALKALOIDS IN CINCHONA BARK.—Prollius observed that if a mixture of 38 grams alcohol, 10 grams chloroform, 2 grams ammonia water, and 5 grams cinchona bark, is agitated in a stoppered bottle, a wine-red liquid is obtained, containing all the cinchona alkaloids. On mixing the clear decanted liquid with 5 grams finely levigated calcium hydrate, it is at once decolorized, and on slow evaporation the quinine is left of a rosinous appearance, while the other alkaloids are crystalline. From the weight of the decanted liquid the weight of the cinchona bark represented therein is easily calculated, and the percentage of alkaloids from the weight of the residue obtained on evaporation. A simpler process for ascertaining the percentage of quinine and of the other alkaloids soluble in ether is as follows: A mixture is made of 88 ether, 4 ammonia water and 8 alcohol, the latter serving merely for uniting the ammonia with the ether. Thirty grams of this mixture are well agitated during several hours with 3 grams powdered cinchona bark. 20 grams of the clear solution, containing the alkaloids in question, and being mixed with a slight excess—5 or 6 drops—of dilute sulphuric acid, separate a thick solution of the alkaloidal salts, from which the ether may be readily decanted; the latter should be well agitated with 2 grams and then with 1 gram of water, in order to obtain all the alkaloids. The mixed aqueous solutions are heated to expel all the alcohol, and, while still warm, precipitated with ammonia. The weight of the precipitate, after washing and drying, multiplied with 50, indicates the percentage of the alkaloids soluble in ether. The alkaloids may also, though less correctly, be weighed as sulphates, if the etherial tincture is freed from ammonia by agitation with water, and then very carefully neutralized with dilute sulphuric acid, when the sulphates will at once crystallize out; a slight excess of acid will readily dissolve these salts.—*Archiv d. Phar.*

A Caterpillar Plague in South Australia is thus noticed by the *Jamestown Agricultural Review* :—"Myriads of caterpillars are making their appearance in the most northern areas."

Rio.—The "Centro da Lavoura e Commercio" proposes to hold another national coffee exhibition in this city during the first half of September next, and for that purpose circulars have been sent out to the planters asking for the remission of samples.—*Rio News.*

Covering for Cinchona Trees.—Our attention has been called to a patent waterproof paper manufactured by a Company in the suburbs of London, which seems admirably adapted to take the place of moss or grass as a means of protection to Cinchona trees after the bark has been stripped. It is light, very easily applied, quite impervious to wet, and by no means expensive. The charge is, we understand, twopence per yard of 54 inches width, so that the cost per tree would be trifling.—*Planters' Gazette.*

A New Vine Disease.—Our travelling contributor, writing from Florence, states that a new disease in the vines has manifested itself in Italy, where it made its first appearance in some vineyards in the neighbourhood of Granarolo. It is an insect locally known as the Apate—the *Sinoxylon muricatum* of entomologists. When it has reached its full growth, it is less than a centimetre (three-eighths of an inch) in length, dark coloured, with a reddish metallic lustre, and somewhat resembling a small fly. It attacks the wood of vines from one to three years old, and bores tunnels in them, which are visible to the naked eye. It exhibits a great predilection for the knots, in which it burrows. Shortly afterwards the leaves, grapes, and branches springing from them dry up and wither away. When it has found a congenial nidus it lays its eggs, and completes its life-work. The Apate ordinarily attacks the weakest plants, but strong and healthy ones do not escape its ravages. The injuries which the insect is capable of inflicting are stated to be so serious as to necessitate the adoption of immediate measures for its destruction whenever it exhibits itself. At present it seems to be uncertain whether the Apate is a novel enemy of the vine-tree, or whether it is one of the many parasites which have from time to time preyed upon it, and which favourable conditions have stimulated into exceptional activity.—Melbourne *Argus.*

Fruit.—The *Monstera deliciosa* is a fruit only requiring to be tasted to be at once appreciated. At present it is a rarity, and but few have had their palates tickled by its exquisite flavour; it may be gratifying to such as have not to know that it is truly delicious, as its name imports. In shape the fruit is something like a very large banana from 8 inches to 9 inches long. It has a scaly rind, which comes off easily when ripe in square pieces, and the eatable portion is a pulp about as soft as a very ripe banana, surrounding a small hard core. The flavour is a blending of the pineapple and the banana, and like the latter fruit for juice, and can hardly fail to please all comers. The plant evidently loves moisture, and is to a great extent a parasite; for in its native habits it runs over and roots on logs on creek sides and in moist places, but it is sufficiently accommodating to thrive fairly in ordinary garden soil, with a good-sized lump of hardwood to cling to. Almost anywhere upon the coast country of Queensland it will succeed, but the more tropical the climate the better it will thrive. It is quite ornamental with its large glossy divided leaves, and, although not a remarkably prolific bearer, should have a place in every good collection. The fruit takes about a twelvemonth from the time it first appears until it ripens, so that patience is called for before it can be enjoyed. —*Queenslander.*

Mysore and Malabar Cardamoms Grown at Rangala.—I beg to thank a correspondent for an entire plant of the Mysore cardamom with one branch of fruits attached to it, and another of the Malabar one. The former is from a plant of 20 months, growth, and is 9½ feet long with very fine clusters of fruits on the flowering stalk, which is 30 inches in length. The Malabar variety is from a plant of 22 months' growth, and measures 8 feet 4 inches, with the fruit stalk 20 inches. The Mysore plant is very robust and evidently a more prolific variety than the other. By a curious coincidence the native gardener in charge of the Government experimental gardens at Henaratgoda showed me on Saturday morning some cardamom plants grown in a corner of the forest under dense shade, and which were loaded with fruits, but he informed me that the fruits had three enemies to contend with, viz., the commonlow country monkey, rats, and grub. The plants were tall, robust, and seemed to be bearing well here, but then the soil and shade in the Henaratgoda gardens are exceptionally good. Some time ago some plants were sent to me with the flowers and fruits growing abnormally in the axils of the upper leaves: can any of your correspondents tell me if this mode of flowering is of rare occurrence, or whether it is common to any variety of the cardamom plant cultivated in Ceylon? —W. F.

A Tea Paradise.—A correspondent sends the following glowing account of some of the country near Adam's Peak as well suited for tea culture :—"Kuruwitte, 27th September.—In view of the increasing demand for Ceylon teas at home, as ascertained through public and private sources, but principally through the latter, all localities suitable for the production of this article should be placed more before the general public, and there are few places in the island more admirably adapted for the cultivation of tea, yet so little known, as the Kuruwitte and Nawadun-korales; they deserve to be taken more notice of than they hitherto have been. This district, perhaps, contains the largest reserves of forest at present available for tea cultivation, and also other new products, not to speak of the chenaed and other lands which, from the extraordinary combination of humidity and heat that obtains here, forcing out great quantities of leaf, are of considerable value. The soil is good, being of a rich surface and a free sandy subsoil, in places of very considerable depth, and good natural drainage. The lay of land is all that could be desired. The rainfall at Ratnapura averages about 150 inches in the year, with a slight increase as one approaches the Adam's Peak range; but, by some influence the precipitous hills exercise on its condensation, it principally falls at night, leaving the days alternating sunshine with showers, and very hot and steamy. The value of this combination for flushing cannot be overrated, and in consequence of the extraordinary absence of wind the flushes are not liable to be checked. The elevation ranges from 100 to 2,000 feet, and higher, if preferred. His Excellency the Governor's opening address to the Council last week gave us the very gratifying intelligence that our wished-for road had been voted; the trace is carried close past what would be likely the great centre of the district. Transport to Colombo would be always reasonable, as the rates for cart hire (the road from Kanapura is 57 miles) would be held in bounds by the option of water-carriage to Kalutara. A further advantage here is that, for a low-lying country, the population is scanty, and thus would not interfere so much with the purchase of large tracts of land. I can confidently predict that, before many years have passed, this district will rank as one of the largest and best tea-producing localities in Ceylon."

SHELL MARL.—A Company has been formed in South Florida, it is said, to manufacture an active fertilizer from the shell marl, which is found in large quantities on some portions of the upper St. Johns. It is proposed to grind the shell, and supply ammonia by adding the decomposed flesh and bones of fish.—*Oil and Drug News.*

PIONEERING IN PERAK.—No doubt the depression and hard times have since of late given an impulse to the sons of Lanka's isle to leave her and their sweet homes, to try their fortune in other climes. Just at this time Perak from far-off hails the so-called prospects to our young friends with the good news that a dollar $ is equal to R2·25 of Ceylon currency, which makes an impression on people to obtain employment at any cost, but they know nothing of the difficulties they will have to undergo because they only see the bright side. I shall now in the interest of my countrymen depict the gloomy side of the picture. Offering employment at Perak on a salary of 50 or 60 $ per mensem and free quarters is looked upon by those in Ceylon as really a chance to make money. I shall make use of the old saying to applicants: "Look before you leap," or else the ditch is near. Now comes the grand question: what kind of a place is Perak, how far from Ceylon, and what are the expenses for living in such a place? Perak is a province in the Straits Settlement and a native state having a Malay Rajah. The sons of the soil are Malays—a wicked and ugly race who would draw their knives for the least thing. Besides these there are a few Tamils and thousands and thousands of Chinese with their pugnose and pigtail. The Europeans are but a handful. The working of the State is carried on by the British, subject to the Rajah, with a Resident who is like the Governor of Ceylon, an Assistant Resident, a few Collectors, a Doctor and his Assistants, a Superintendent of Public Works, and Surveyors with a few assistants, a public office with a few clerks, a force of Sikhs, some constables, a jail and jailor, and some bazaars with the exception of a number of mines ("lead:") everything else is jungle. The distance from this to Ceylon is about 1,058 miles, 1,050 by sea and river, and 8 miles by land. Penang is the first landing-place when you leave Ceylon, and the proximate cost is passage Colombo to Penang R100 to R130 second-class, boat hire R50, guide R2 25, carriage R1·12, cart hire and luggage, R2·25, the lowest hotel charges for the day R13·25. From Penang to Larut:—Carriage R1·12, cart hire for luggage R2·25, boat and steam tug R3·87 and from thence to Thaipeng, the chief station, of Perak, carriage and cooly hire R4·87, and resthouse charges R2·50, attendance and bath R1·12 for the day. Then comes the cost of different things:—washing 8c a piece, a crop 60c, a shave 41c, scavenging 25c a day, a bath 40c, a cook R25·00 (or 10$) a month, who will do no other work. In short, every servant you engage will have to pay 10$. Meat or mutton cannot be got, but buffalo meat which is sold two or three times a week at 40c per lb, fowls of small size 60 to 100c each, eggs 8c each, ducks R2 to R2·25 each, pork 40c to 50c a lb, river fish 30c a lb, all dry and fresh fish is sold by weight counts 12c each, onions 20c. a lb, chillies 25c a lb, (rice 20c a measure), eating this is similar to eating straw, firewood for cooking 25c a day, a pair of shoes R4, a white "drill" suit R7, an ordinary tweed suit 35$ or R77 62. In like manner everything else is dear, no sea fish' maldive fish, plantains, hoppers, &c., &c., to be got; buy some liniad. As for the dainties and luxuries of Ceylon you will ever have to pine. Taking up appointments in Perak for 75$ which is equal to R198·75 is only offering oneself for voluntary banishment for life. In bygone days convicts of Ceylon were sent to the Straits and it was considered as a great punishment. 60 or 70$ is hardly sufficient to live upons, so how can you manage to get back to your native country except you get money from home, otherwise end your days in sorrow and cares?—*Cor.* [Hoot, toot; this will never do for a young Ceylonese emigrant.—ED.]

EFFECTS OF THE RED SPIDER.—The destructive effects of this pest will best be understood by a reference to the figures taken from the published reports of the Leebong Tea Co. In 1875 the out-turn was 4000 mds., but since 1878, the advent of the red spider, the out-turn from the original gardens has fallen to 2,600 mds.—*Indian Tea Gazette.*

THE CONGRESS ON THE PHYLLOXERA have arrived at no very practical result. It seems to be held that those who have the means of submerging their vines for at least forty-five days continuously in water may cure their vines of the insect plague, though we do not know that they would not be liable to a reinvasion by it. But very few have the means of managing this immersion, and if they had, a great many of the vines are found to be injured as fruit-bearing trees by the process. Again, sulphuret of carbon and sulphocarbonate of potash kill a great many of the insects, if the roots of the vine be well impregnated with either; but the cost of the first is £18 per acre the first year and £12 afterwards, and of the second, £28 an acre the first year, and £20 an acre afterwards. Neither does either remedy, costly as it is, ensure the plant against insects. Completely killing out the infected vines and importing new kinds seems the best chance: but that, again, means an enormous waste of capital.—*Spectator.*

TEA IN NORTHERN INDIA.—The Duars, or as sometimes called, the Bhootan Duars, is a belt of forest and jungle land, stretching out from the foot of the Darjeeling and Bhootan Hills along the banks of the river Teesta, on to the borders of the Assam districts. This very fertile tract of country belonged to the Deb Rajahs of Bhootan; but after the Bhootan war of 1864, the territory was ceded to the British. Early in the season of 1874 75, applications were made, by a few planters, for land in the Western Duars; and in due course, clearings were made here and there, and tea gardens sprung up. The country is very favourable for the growth of tea, as its soil is rich and loamy, well manured by decayed vegetation, which has lain there for ages. The aboriginal inhabitants of the country are the *Machies*, a tribe of people very much allied to the Assamese, whom they resemble in features and habits. Their mode of cultivation very disastrous to the forest tracts. The *Machies* are useless as labourers for tea gardens. They simply refuse to work. All the labour has to be imported, and the Nepalese coolies are found to be the best workers. At the present time there are a good number of tea gardens scattered over a large area of country; and the manufacture of tea has been going on for the last five years. A glance at the tea sale reports will show that the prices realized for the Duar teas are, on an average, much higher than the prices obtained for tea from the Terai, or the Darjeeling district. Possibly this is due to the richness of the land, and hence a finer crop of leaves. From the latest information received from the Duars, it would appear that there are no less than 500 applications for land lying in the Commissioner's office; and it is quite possible that, within a very short period, the whole of the country will have become a continuous string of tea gardens. As to sport, the district abounds with game of nearly every description, from the elephant downwards: and we would recommend it as a good shooting ground for sportsmen during the cold weather.—*Civil and Military Gazette.* [The great disadvantage of the Duars is that against which planters in the Terai and in many parts of Assam and Cachar have to struggle, apestiferous climate.—ED.]

MR. DE SOYSA'S RICE, GROWN AT HANGURANKETTE, has been tried by us in broth and with curry, and we can only say we wish we and our readers could always be supplied with grain so plump, so clean and white and so nutritious. It is the greatest possible contrast to the stuff generally supplied to the coolies and to much of what is seen in the bazaars. Rice like that produced at Hangurankette ought to command a good price in the market, in comparison with much of the imported grain.

GENERAL BISSET'S Farming Scheme in Natal does not seem to be a success, at least so far as the gentleman pupils are concerned; the report of the case between pupil and master which we took over from a Natal paper, besides being interesting and even amusing in itself, reveals to us a good deal of the life encountered by a pioneer farmer in South Africa, and indeed the work which the young gentlemen in this case, found too hard, is just what has to be faced in any of our farming colonies.

A MONSTER YAM.—The *Fiji Times* has the following paragraph :—A correspondent from Taviuni has forwarded to this office for inspection a tikau, a species of wild yam, which one of his men lately dug out of the bush at the back of his homestead on that island. The tuber is 4ft 8in. in length, 2ft. 1in. in girth, has a spread of 2ft. 5in. in the fork, and weighs 35lb. That it should have attained to such a size without cultivation or care is the best proof that can possibly be given of the extraordinarily productive power of the soil in which it was grown, and it well maintains the reputation of Taviuni as the most fertile island of the group. The gentleman who forwards it modestly styles it a "tivoli," and naively observes : "This is larger than the men *ordinarily* bring in."

TIN TEA BOXES.—We have received from Messrs. Wm. Law & Co. papers referring to Messrs. Harvey Bros. and Tylor's tin tea boxes, for which they are the agents. One paper gives colored representations of the different sized boxes (from 1 lb. to 20 lb.) and another gives minute directions for making up the tins, while a third quotes Col. Money's article from the *Indian Tea Gazette* of 20th October 1880, and a letter by a tea planter in the London *Times* complaining of the loss of weight to the importer in weighing teas on their arrival in England which the use of these boxes of obviates. Messrs. Harvey Bros. and Tyler say in reference to these boxes :—" Owing to the great success which has attended the introduction of these decorated boxes (*with China designs*) to Australia,* especially the smaller sizes, we have had boxes made with Indian designs to contain 6 lb. and 12 lb. of tea. These we should recommend being used along with the larger size. It will, of course, be understood that the weight of tea in every box varies according to the description of tea packed ; for instance, a box holding 12 lb. of bold-leaf pekoe souchong may hold 16 to 18 lb. of fine pekoe or broken tea. In this way the cost per pound is considerably reduced. We have little to add to what has been said by Colonel Money, and can only repeat that the advantages these boxes possess are—1. the improved condition of the tea in transit ; 2. the uniformity of tare insured, and thereby the reduction of loss in weight to a minimum ; 3. the introduction of an increased sale in other markets than England for Indian tea ; 4. the probability of Indian tea reaching the consumer in an unadulterated condition in such convenient packages as 20 lb., 12 lb. and 6 lb. boxes ; 5. the facility with which the boxes can be put together, and their ornamental appearance and utility when they are emptied of tea." Certainly those boxes seem to have great advantages over the wooden cases, and we shall be surprized if they do notultimately supersede the latter.

TEA GROWN NEAR GALLE AND HIGHER UP.—A short time ago Mr. Zeigan, of the P. & O. Company's service, gave us specimens of pekoe and pekoe souchong, the produce of his land in the valley of the Gintara, about twelve miles from Galle. The tea had a newish taste, but was good in quality and the pekoe especially remarkable for strength. The samples, like most others which reach us, shew that tea will grow well in Ceylon from sea-level to 7,000 feet. Yesterday we supplied Mr. A. B. Inglis (late of the great Calcutta tea firm of Begg, Dunlop & Co.) with a cup of tea from a property nearly 6,000 feet higher than Mr. Zeigan's and he said that a nicer tea there could not be. Most part of the teas of Ceylon, like those of Darjiling, will be sought on their own merits and not so much to be mixed with China.

FIGS from the earliest ages have been held in great repute. In a primitive condition of society they served to furnish the nations of the East with an article, not of occasional luxruy, but of daily and constant food. So highly were they esteemed by the Atheoians that their exportation was prohibited under a heavy penalty. In Rome they were carried after the wine in the processions in honour of Bacchus, and the old gentleman himself is supposed to havo owed his corpulance and vigour not to the grape but to the fig. By the Jews a bad fig year is regarded as a most serious calamity. Fresh figs, when ripe, are soft and succulent, and are degestible, wholesome, and delicious fruit, which may be used with advantage in habitual constipation. When the fresh fruit is not obtainable, we must be satisfied with the dry, although as a medicinal agent it is far less efficacious.—*The Family Physician for June.*

KAOLIN.—In his report on the geology of the North Arcot District, Mr. Bruce Foote writes :—"The highly felspathic varieties of the granite gneiss are occasionally so greatly decomposed as to appear to offer sources for the collection of kaolin or China clay. When carrying on the survey of the Vellore and Gudiyatam Taluks, I noticed various spots which appeared to me to be deserving of attention with this object till I had seen some of the great China clay works in Cornwall, which I visited specially for the purpose study when at home in 1868. The conclusion I then came to was, that none of the North Arcot localities showed rocks sufficiently rich in decomposed felspar to be of much importance. The extent to which the Indian rocks have been penetrated by decomposition is greatly less than the Cornish rocks, and the quantity of clay which would therefore be procurable in India would, area for area, be greatly smaller than in Cornwall. Added to this very serious disadvantage is the difficulty of a suitable water-supply. To insure the preparation of kaolin of good color, which alone commands a high price, a very large supply of perfectly limpid water is a *sine qua non*. This is not always easy to obtain, even in a rainy climate like that of the south-west of England, where running streams are of frequent occurrence, and in a dry climate like that of the Carnatic this want could only be met by the construction of special reservoirs of large size, in which the water could be allowed to stand for many months after the rainy season till all the suspended particles of ferruginous clay had settled, and the water itself has become perfectly limpid. If the great cost of providing such supplies of limpid water free from saline matter in an eminently dry country be taken into consideration, together with the fact that the kaoliniferous decomposed rock occurs in greatly smaller quantity, and is generally much less free from ferruginous staining due to the filtration through the almost universally overlying red soil, the conclusion seems inevitable that the prospects of establishing profitable China clay works in North Arcot are not very promising.—*Madras Mail.*

AGRICULTURE ON THE CONTINENT OF EUROPE.

(Special Letter.)

NITRATES, PHOSPHATES, POTASH AND SOILS.

PARIS, September 9.

What is the true theory of a rotation of cropping? Doctors differ on the point: there is a school in this country that reduces the question of the fertility of the soil to a matter of strange give and take. Here, they say, is a general table of analyses of soils and also of cultivated crops: of certain manures, &c. Nothing is easier than to calculate the total yield of a crop, to know the quantity of phosphates and of potash, &c., carried off: the analysis of the manure will enable the quantity of these salts to be estimated and requisite to be returned to the soil: if in excess, the richness of the land will be augmented. It is further laid down that cereals and industrial plants draw largely on the soil for nitrogenous principles, but as the crops are succeeded by forage plants, the deficit is made up by the intervention (hypothetical) of atmospheric azote. Further: the necessity to practise a rotation of cropping is explained by plants not requiring the same mineral substances, so that, what one leaves the other will appropriate, and that after a lapse say of five years. Thanks to periodical manurings and dissimiliarity of tillages, the alternate exhaustion and the renovation of the soil will be found equalized.

Now what is our stock of precise, demonstrated knowledge on this subject of rotation? It is exact: that the mineral food removed must be restored. By the successive cropping of lands in Sicily with wheat, the phosphates had been exhausted, and the soil has become impoverished. The same fact was in process of realization in the north of France, till M. Corenninder called attention to the necessity of employing phosphates, and since fertility has returned. Now for plants, as for manures, there is no constancy either in mineral or nitrogenous, or even in any other elements. Analysis shews that a large number of different manures vary in composition; from one to four times in the case of the same element. Similarly for plants; wheat for example, where the percentage of nitrogen, as in gluton, varies from one to three, there are analogous differences for the potash and phosphoric acid carried off. Hence, there is no mean, no Procrustean standard, that can be declared off land, applicable to a special soil. Strictly speaking, each particular case demands a new analysis; one field may produce a forage five times more nutritive than another.

A popular error exists that. Boussingault asserted that forage plants take nitrogen directly from the air, but even his latest experiments demonstrate the exact contrary. Then the attempt has been made to explain the restitution of nitrogen to the soil by the agency of meteors and rain. It is a fact that ammoniacal salts and nitrates are constantly present in the air, and conveyed along with other saline and dust matters to the soil by the rain. But the latter falls on the just and unjust alike; upon all cultures indistinctly, not upon any particular rotation, and not specially on forage plants. It is assumed, but not proven, that electricity nitrifies the azote of the air in the interior of the soil by a union with hydro-carbonaceous matters; or effects a similar end in the interior of plants by their starch, sugar &c. We know, however that the azoteous matters in the soil can be nitrified, but that is not an augmentation of richness; also, Cavendish has shown in 1784 that an electric spark, traversing an atmosphe, enriched with oxygen, can produce nitric acid. Now if electricity makes ammoniacal salts and nitrates in the atmosphere, that intervention is for all rotations and crops alike.

It may be laid down as an axiom that every system of culture which does not bring from an outside source the materials—whether nitrates, phosphates or potash, &c.—rare in a soil and carried off by the produce, must ultimately suffer in fecundity. There is a necessity, apart from these food considerations, to rotate crops. The plan affords the means for extirpating weeds, for cleaning the ground, and of destroying insects, since, if the latter, peculiar to a distinct crop, be deprived of its special food for one or two years, it must die of starvation. To keep a soil rich, depend upon manure rather than on—the air.

The extent of vineyards in France is 4½ million acres. One-quarter of this area is invaded by the phylloxera, and the new ravages of the insect are estimated at the rate of 200,000 acres annually. Three official remedies are recognized: sulp-carbonate of potassium and sulphuret of carbon, submersion, and American stocks for grafting on the affected vines. To these must be added a relatively high manuring. It has been found that purely nitrogenous manures, as wool clippings, horn parings, dried blood, oil cakes, &c., develop the vine at the expense of the fruit; but farmyard manure, or a composition of potash salts, soluble phosphates, and a proportionate dose of azoteous matters have the opposite effect. A high authority, M. Rommier, recommends a new and cheap insecticide—bi-sulpho-carbonate; he also recommends the summer floodings of vineyards. He doubts the efficacy of autumnal irrigations, because at that period the bug is prepared for its hivernal sleep, is encased in a kind of wax waterproof, and has a sufficient provision of air to guard against being drowned. Even M. Faucon, to make the submersion process more certain, has had to prolong the floodings to 45 consecutive days. Some persons of late dissolve the insecticide in the water intended for irrigating the vines.

In several parts of France, and notably in the southern vine making districts, the residue of the grapes, after being pressed or distilled, is conserved in cement cisterns for cattle feeding; the layers, of 12 inches, are dusted with salt, the whole when pressed down being covered with puddled clay: occasionally the latter is represented by a thin sheet of weak brine. Some people take the stalks out of the residuum, as the mass then keeps better. Stock relish the feed from its alcoholic flavour, and is given similarly to beet pulp. In the district of Mont-d'Or, famous for its cheese, prepared from sheep's milk, the sheep are house fed all the year round; in summer, &c., on the leaves of the vine, and in winter on the residue of the winepress. In Germany, brewers' grains are similarly preserved as the grape residue, save, that the cistern has a cover battened down on the grains, being itself covered by a layer of water 8 inches deep.

The beet crop has been attacked by the same fungus this year as in 1852; it is a species of mushroom that settles on the leaves, producing a kind of rust. In some cases all the leaves had been destroyed; in others, new leaves had succeeded. On analyzing the root, it was found to have suffered to the extent of 3 per cent in richness as compared with healthy roots.

Water-distributing flexible pipes are generally lengthened or joined by the additions screwing together. M. Beaume simply arranges that one end of the pipe passes into that of the other, the union being secured by a lever, which locks; an indiarubber ring prevents all leakage.

French farmers are becoming also manufacturers: thus, the distillation of molasses, of maize, and of beet, has been improved by employing the electrolyseur, which sends an electric current into the mass that decomposes the water; the liberated oxygen then displays an affinity for foreign products of objectionable taste and burning them. It is thus that beet brandy has been debarrassed of its bad flavour; the first shot distillation yields 75 per cent. An electrolyseur will produce 4,000 gallons of brandy in 24 hours.

AMERICAN BLIGHT ON APPLE TREES.

A practical gardener and horticulturist supplies us with the following cure for American blight on apple trees :—The best time for operating on the trees is the end of May or the beginning of June. Bare the roots of the affected trees of soil, and leave them exposed for a few days to the air. Prepare a wash composed as follows :—Boil 1 lb. of tobacco in a covered saucepan for an hour in two quarts of water. Strain off the water for use. Make into a paste, with warm water, 2 lb. of soap, 2 lb. of flour of sulphur, and a gill of turpentine. Mix this paste up well in the tobacco water, and add as much more warm water as will bring the whole mixture up to five gallons. Then scrape off all the rough diseased bark from the stem of the trees, and with a hard brush scrub the trees with the wash, which should be applied warm, say at a temperature of 115 degrees. Then saturate the soil you have drawn away from the roots with ammoniacal liquor from a gas-works, or if you cannot get that, use stale urine (a month old), or a strong brine of common salt, and return to the roots the soil so saturated again. With this treatment I have always managed to destroy the blight, and keep my trees in healthy condition. [Treatment which, in a modified form, might be found useful as a remedy for blights on fruit-trees in Ceylon.—ED.]

ESTIMATE OF THE COST OF PRODUCTION OF CEYLON TEA.

The manager of one of the largest tea "conservs" in Ceylon writes :—

"I enclose this year's estimate in rough : if there is any information you are welcome to it. The charges in some cases are high, but I have to make preparation for making other 40,000 *bought leaf* : hence *the machine* and additions."

ROUGH ESTIMATE FOR 1882-3 :—

Salaries :—Europeau ... ... 250·00
Do. Conductor 40 00
Do. Tea house man ... 25·00 = 3,780·00 or 9·450.

Allowance, 2 men per day on an average R21 per month or for 12 months R252—·630

Weeding 160 acres at 1·76 per acre = R3,384·00—8·40

Pruning 135 acres 5 × 5 = 235,170 trees and 25 acres 4 × 4 = 68,025 or 303,195 trees at 150 trees per man, 2,021 men = R666·93 or 4·27 per acre ; if it can be done for that.—1·667.

Roads :—Upkeep of estate roads. Road to the gap ½ share repairing culverts, &c., R150·00—·375.

Drains :—Keeping clean and blasting stones R1 per acre R160—·400. [After indicating that repairs will be needed for stores, bungalows and lines, the writer proceeds as below.]

Cattle grazing 32 head, cutting bedding and grass 3 men per day R368 28—·927.

Firewood :—320 cubic yards required for 40,000 lb tea, and it costs 75 cents per yard delivered in Factory, or R240·00 or ½ cent per lb —·600.

Plucking :—160,000 lb green leaf at 2 cents per lb, women for the past year having averaged 16 lb per day, R3200·00 or 8 cents per lb tea.

Withering :—One man every night as watchman and witherer R120—·4 .

Rolling :—On an average 44 men per month, R174 24 —·433.

Drying :—On an average 52 men per month 205·92 —·510

Sifting —Cleaning out red leaf and sorting 400·00 —1·000 a pound.

This estimate is for 40,000 lb tea or 3¼ maunds per acre. I might make 50,000, if I could guarantee *cash and labor*.

Cost of redrying, packing in boxes, soldering linings solder, sheet lead, closing boxes and hooping them 1½ cents per lb. R600—1·500.

Cost of boxes in Colombo 1·80 say R2 put together, and, as the average weight often in boxes is 90 lb., 450 boxes roughly would be required R900,00 or 2¼ cents per lb.

Carriage :—About same as last year, lead, solder, nails, machinery, store charges, &c., R180—·450.

Despatch carrying boxes to Gap at 15 cents per box or for 450 chests R67·50.

Tea chest average weight is 114 lb. gross and 450 weigh 51,300 lb. or 23 tons, and rail freight is 14 70 per ton R338·10—·845.

Cart hire to Nawalapitiya 23 tons at 9—R207.

Tools :—New drying machine say £87-00-00 in London and at 1s 8d it comes to R1,032—landed at estate cannot say. [It will certainly cost R1,300.—Ed. C. O.]

Other tools :—Repairing vetta cutties, repairing forks &c., R100.

Contingencies :—Medical Assessment R80, stationery R20, Dolosbage road, estate books, report forms, &c. Hospital charges.

Charcoal for heating store for withering about 100 maunds at R1 per maund R100.

All the lead, hoop-iron, solder, &c., was taken at the rate three years ago, but instead of R25 a cwt., for lead it cost this year 13 to 17 only ; weeding is high ; also my pay may appear high on 156 acres, but then it is the outside leaf that raises certain charges.

MADRAS GOVERNMENT FARMS.

PADDY—SUGAR-CANE—ARROWROOT—TOBACCO—CASUARIANA.

(From the *Madras Mail* Sept. 29th.)

We have only now received a set of three reports for 1880-81, submitted to the Government in June, July, and September of *last year*, by Mr. W. R. Robertson, Superintendent of the Government Farms. Fodder crops were raised on an area of 36 65 acres. Further experience confirmed the opinion long ago expressed that South-India is remarkably rich in the possession of fodder crops suited to the different soils, and the widely differing conditions of climate which characterize the cropping seasons. It is worthy of notice that, in so short a growing period as six weeks, fair crops of fodder were provided. We notice

that of the unirrigated cereals the *sorghum saccharatum* gaveja poor crop owing to the unusually heavy rain and the low temperature. On the other hand the Planter's Friend, which is closely allied to the *sorghum sacch.*, did remarkably well. This crop is evidently a hardy one, and capable of withstanding adverse conditions that would prove disastrous to a crop of *sorghum sacch.* Irrigated cereal food crops were raised on an area of 16·63 acres of land irrigable from the Mylapore tank. On most of the land two crops were raised, the latter ones being watered in later stages of their growth, by baling, the tank water not then being available at a sufficient height to admit of it flowing on the land. For some of these second crops sufficient water could not be got, and the out-turn from them was accordingly considerably lessened. The total area of crop raised to maturity was 26·82 acres. 26,517lb. of grain, and 67,067lb. of straw were in a period of seven months produced on 16·63 acres; the average out-turn per acre being thus, grain 1,594lb., and straw 4,033lb. As has already been noticed, much of this crop was second crop, which, from unavoilable circumstances, did not receive as good treatment as was desirable. However, how many of our native paddy growers can show such results? Some interesting facts are elicted with regard to sugar-cane. The land occupied with this crop was planted with cane on the 21st December 1879. The land had previously carried plantains, and during their growth had been brought into a fair condition. The soil however, like the soils of the farm generally, is naturally poor. Early in December powdered bones were applied broad cast and ploughed in just before trenching for planting. In April slaughter house refuse was applied. In August 1270 canes were taken out for use as seed cane in another field of the farm, and again in November 304 canes were removed for the same purpose. By the end of December the canes were ready to cut. "Some of the canes were sold standing; a row 80 yards long being sold for R. 2-4-0, or at the rate of R. 136-2-0 per acre." Such a statement as this, the result of the sale of one single solitary row of canes, is of very little value. The statistics which follow, though, are of importance:—during January and the early part of February, the whole crop was removed, and the greater part crushed in one of Thomson and Mylne's beheea Sugar mills, and the juice boiled down into jaggery. Canes weighing 12,383 lb. were crushed, and yielded 780¼ lb. which sold for R. 46-9-0. The yield of jaggery from an average row of cane was about 34 lb., worth R. 2-0-4. The result showed that it is more profitable here to sell the canes standing for retail sale in the bazaar, and that on soil of the nature of that in the field where this crop was raised, the crop does better in every way if planted in rows only three feet and not six feet apart. The result of careful cultivation was that the farm-grown canes produced much more juice and much more jaggery than canes which were purchased in the neighbourhood for the sake of comparison.

What Mr. Robertson writes about arrowroot should be read by our agricultural readers, especially natives, and we give the whole paragraph:—

Arrowroot (*Curcuma angustifolia*).—A plot measuring ·25 acre was planted with this crop at the end of 1879, and remained down during the year under report. It was taken up at the end of January last and yielded 986 lb. of tubers or at the rate of 3,944 lb. per acre. The yield of flour obtained has generally been about 12½ lb from 100 lb of tubers, so that the above yield would represent an outturn of 493 lb. of flour per acre. In another case in the College Experimental Garden, a plot measuring 1,160 square yards planted with this crop yielded 1,798 lb. or at the rate of 7,500 lb. per acre. The culture of this crop is very simple: it is only necessary to plant the sets in properly-prepared soil, and to water them occasionally during the dry season. The removal of the crop is tedious unless the tubers can be ploughed out, as potatoes are done in England, which is seldom possible owing to the dryness of the soil, so that the tubers have to be dug up. The preparation of the flour is also very simple and easy. The tubers have only to be reduced to pulp on a grater, after being well washed to remove soil and dirt, and then the pulp is mixed thoroughly with water so as to separate the starch completely from the fibrous matters. The whole is afterwards strained through cloth, through which the starch and water passes, and the fibre left behind. After this the starch has only to be thoroughly washed by decantation with clean water, and dried in the sun. It is then rolled on a table to break it up thoroughly into fine flour and is ready for sale. The flour can be produced at a very low price; it could be sold profitably at 4 annas per pound.

The results of the analysis of tobacco grown on the farm show how much the farm soils have been improved by careful cultivation. Smokers will be interested to learn that

On the proportion of organic salts of potash in the leaf the "whiteness and permanency of the ash of a cigar depend," and their presence also "modifies the burning of tobacco in a peculiar way, to the improvement of its flavour, and also positively facilitates burning." In real Manilla tobacco the amount of this substance is above 9 per cent, whilst the ash of the best American tobaccos often contains from 25 to 35 per cent rent.

Having been agreeably surprized to see what a change has been created in the neighbourhood bordering the road to Ennore by the successful planting of casuarina trees, we were pleased to find some remarks about casuarinas in the Saidapet Report. We read:—

The *casuarina trees* planted in 1878-79 continued to progress well during the year, many of them making a great growth; they are now nearly safe from the effects of bad seasons. Those planted in 1879-80 have also done very well on the whole, most of them having been manured early in the year. The watering required was but little, owing to the shade and protection afforded by the dholl sown between the lines for the purpose. One large plot (5 acres) was planted in three portions; in one portion the rows of trees were 4 feet apart and the trees 3 feet apart in the rows; in another the rows were 4 feet and the trees 4½ feet apart and in the third the rows were 6 feet and the trees 6 feet apart. Of these, the first portion have done much the best, and the last much the worst; but the latter portion is situated on the poorest portion of the field, and many blanks occurred from deaths, which had to be replanted during the year.

Various causes combined to spoil the effect of the manuring experiments, but careful notes are being taken to afford information in this direction next year and in following years.

The Aden cow referred to in the last report continued to yield large quantities of milk, and a carefully kept record of cost and of the amount received for milk and calves prove how profitable the breed may be made. Since the report was submitted, a fresh consignment of cattle of this breed has been received from Aden. Some steps have been taken to improve the breed of indigenous sheep, but much remains to be done in this direction, and Mr. Robertson recommends the importation of a few merino sheep from Australia.

Upon a farm used for such experimental purposes one cannot expect a profit. As Mr. Robertson writes,

It must be obvious to all who have given the matter a moment's thought, that the interest the

State has in the working of experimental Farms, is far greater than is represented by the sum it is possible to obtain by the sale of produce raised thereon; else, it would be far better for the State to refrain from engaging in such undertakings, and to seek other investments for the capital on which a mercantile return is sought. Experimental farming is very different from ordinary farming. The cost of the farm might be reduced were the Commissariat slaughter-yards, so frequently complained of, closed and the buildings made available to the farm, as was approved of some years ago. We have shown, again and again, how remunerative dairy farming is here; but we have been unable to undertake this branch of our work, chiefly, because we do not feel justified in keeping a number of valuable cows at the farm, exposed, as they would be, to frequent attacks of disease brought by the slaughter-house cattle. From our inability to engage in dairy farming and stock-rearing, which would so specially suit our soils and circumstances, with the direct loss, by deaths, of stock during the year, traceable to disease, which could have reached the farm stock only through the medium of the Commissariat stock, our annual loss would represent a sum quite equal to 30 per cent of the net annual cost of the farm. However, as long as the objects of the farm are, as at present, experimental and educational, its maintenance must necessarily involve some expense to the State.

Referring to these remarks the Board of revenue observe that in his report for the previous year Mr. Benson stated that he proposed to set apart certain fields on the northern side of the firm to be worked as a commercial or model as distinguished from an experimental farm. The present report does not show that this intention has been carried out, and the Board again invite Mr. Robertson's attention to the matter, repeating their opinion regarding the beneficial effect upon ryots of demonstrating to them that our methods of farming are, from a financial point of view, better than theirs.

EXPORT OF COFFEE AND PEPPER FROM THE WEST COAST OF INDIA.

The table we publish on page 427, includes, in the case of coffee, nearly the whole of the exports from Southern India, as but a small quantity goes from Madras, and we suppose not much from Allepey, Tuticorin and Coimbatore. It will be observed that Messrs. Alstons & Co. trace deterioration of the Mysore native coffee to the introduction of Coorg plants. Why? Our experience in Ceylon seems to indicate that soil and climate have more to do with the quality of coffee than variety of plant (Liberian coffee is a different species). We could understand European planters introducing plants from other districts, but the natives of Mysore must be more reflective and enterprizing than ours in Ceylon, if they voluntarily import plants from other districts. That they should supersede their own plants by others of an inferior class is, however, beyond measure strange, and we should be glad to have an explanation of the enigma propounded by Messrs. Alstons & Co. There is a distinction made in their figures between plantation and native only in the case of some of the ports, and the quantity of this kind seems insignificant. Looking at the aggregate totals we find that the fluctuations are such as might occur if leaf-disease had never made its appearance. The West Coast season ends with June, three months earlier than the close of ours, but the difference is not very material. The question now is: Will there be a fair average crop in the season which commenced on 1st July? If such should be the case, then it will be evident that leaf-disease in Southern India has not told so disastrously as in Ceylon. And yet we have heard sad tales of estates in Wynaad abandoned. Pepper, it seems, is all native grown, but it is possible that the culture may pay the few Europeans in Ceylon who have taken it up, in view of the fact that warfare in Achin seems to have revived and is likely to be indefinitely protracted. The possession of the chief pepper grounds in the world have cost and are likely to cost our Dutch neighbours more lives and money than they are worth. But prestige has also to be sustained. Curiously enough, the transaction between the British and Dutch Governments, by which, in exchange for a small Dutch colony in Western Africa, we gave up the grand island of Sumatra entirely to the Dutch, involved both nations in little wars. Ours against Ashantee was speedily concluded by the man who is now the hero of Egypt. General after General, on the contrary, has returned with a shattered reputation from the war in "Atjeh," as the Dutch call Achin. Governor Loudon sent too small a force to begin with and an officer, whom he censured for not doing what the officer pleaded was impossible, got himself removed from the Army "with honour," for the insubordination of refusing to take the hand which the Governor-General extended to him on landing at Batavia. He gave a formal military salute instead and got shelved. Such are the consequences due to pepper and the mental idiosyncracy to which the spice gives the name of "peppery!"

THE ALOE FIBRE ENTERPRIZE IN MAURITIUS.

Through the medium of a Natal paper, containing report of the proceedings of the Victoria Planters' Association, we are, at length, in possession of distinct information as to the species of aloe from which the planters of Mauritius obtain the fibre which they sell as a rival to hemp. It is the green aloe, *Fourcroya gigantea*, so well-known in Ceylon, especially as a hedge plant for coffee estates exposed to cattle trespass. We have not, to our recollection, before seen the alternative name, *agave fœtida* by which it seems to be known in Mauritius. The industry in that island—the aloes being probably grown on exhausted sugar land—must have assumed considerable importance from the fact that a M. Evenor de Chazal has published an elaborate book on the subject, giving sketches of the machinery employed. This, we regret to observe, is elaborate and expensive, costing from £1,000 to £1,200, apart from the necessary buildings which would, probably, double the amount. A brother of M. de Chazal, who resides in Natal, thus describes the machinery used in Mauritius:—

A small mill able to do half a ton of fibre would contain the following machinery:—1. One boiler of 30-horse power. 2. One engine of 18-horse power; 3. Six apparatus to card, commonly called scrapers. the whole of which would amount, in Mauritius, to £1,000 or £1,200 sterling. According to the produce established above, this mill could manufacture daily 33 tons of aloe leaves.

The machinery being so costly* and it being certain that even if a considerable space could be at once

* At the same time, no doubt there are steam engines in the country at present comparatively idle, which would be available.—ED.

planted, four or five years would elapse before the planter would get any appreciable returns, the Chairman of the Victoria Association naturally objected to the diversion of attention from sugar, about which they knew, to an experimental and costly enterprize like this. When their sugar grounds were exhausted, the case might be different. From the fifth to the eighth year the return of leaves per acre would be about 40 to 75 tons, yielding about 1½ of clean fibre, which would realize about £40 per ton. Other estimates of fibre run up to twice the quantity indicated, but we suspect the more moderate estimate, is the more reliable, both in the case of leaf and fibre. We have had a good deal of personal experience of the green aloe, and we know that it grows readily in most soils, growing of course most luxuriantly in good soils. It yields large quantities of leaves, but the more frequently they are cut, the more is the flowering, seeding,—and dying stages in the plant's life history hastened. A green aloe left untouched might make twelve years of growth before the flower stalk (which shoots up at the rate of half-an-inch an hour or faster) appeared. But the same plant rigidly pruned of its lower leaves would have its life shortened to seven years. On the other hand the reproductive powers of the plant are wonderful and the mode of perpetuation very curious. The stalk of an aloe in flower somewhat resembles that of the talipot palm, the flowers along the stalk being of a delicate primrose colour. We have talked of the seeding stage, but there are really no seeds. The flowers gradually turn green, the petals assuming the form of leaves springing from a bulb, which as it enlarges becomes loosened from the stalk, until a breeze of wind or a shake sends down a shower of miniature but perfect plants, which root the moment they touch the ground. We should think that one flower stalk would yield a full thousand of such little plants. But when the whole of the young plants have matured, the old plant has to be rooted up and replaced and it might be a question whether a good second crop would flourish on the same soil. Perhaps some of our readers —say Mr. John Stephens, of the Diggings, near Gampola, whose estate at one time was fenced with splendid green aloe hedges—can give definite information on this point. It is claimed for the green aloe that not only will it flourish on dry sandy soil, but that it is unaffected by disease or insects. We should have agreed to this, as far as our personal observation goes, but that about a dozen years ago, we heard of the result of an experiment on patena land belonging to Meddekumbera estate, the great Dimbula property of the Ceylon Company Limited. A patch of patena land was properly hoed and planted with aloes, but the plants were exterminated by grubs. So that to these destructive insects the most delicate Ledgerianas and the most fibrous aloe leaves seem to be alike acceptable. The possibility of damage and destruction by insects must therefore be taken into account. If all that Mr. Christy of London says in favour of Ekman's pateut process of dealing with fibrous plants is sustained on trial, then, probably, the objection to the extent and the cost of machinery can be obviated. But it might not be easy at once to obtain large supplies of plants and there would be at least three years to wait for the first returns from a plant, the life of which would be shortened in proportion to the extent to which it was deprived of its leaves. M. de Chazal of Natal states that :—

"The kind of aloe cultivated by preference in Mauritius is the *agave fœtida*, called *fourcroya gigantea*, or roughly called green aloe. Aloe is planted in any season of the year, in furrows 5 ft. distant from each other; 1,600 or 2,000 aloe plants will cover an acre of land. Young plants, or those having two or three years' growth, might be taken for the plantation; however, seeds are much better, but in this case the crop can only be done when they are five years' old. The aloe arrows when it is seven or eight years' old, and can be cut four or five times before it stems; when it has reached this period, the plant must be renewed.

"Comparing aloe plantation with cane plantation, the former can be done with less expense. A simple tilling would do; moreover, sandy, or loamy lands would do perfectly well. I think that as soon as the plant has grown it might be left to itself, without weeding, until the crop takes place.

"The produce of the fibre in one acre of aloe would be about one ton and a half, the price of which varies from £30 to £40 the ton, and still tends to rise. Nothing is certain concerning the real richness of the fibre in the leaf of the aloe, the estimates vary from 3½ per cent to 8 per cent. With the last improvements brought in to Mauritius, they have succeeded in getting three pounds of fibre to 100 pounds of leaves; but according to the system of counting in Mauritius an average of five pounds has been reached."

Four or five annual crops of leaves, therefore, appear to be the returns which can be safely calculated on, provided the cochchafer grubs or other pests do not interfere. We do not know that weeding would be necessary, but as a general rule the liability to fungoid or insect pests is in proportion to weediness. Dr. Sutherland of Natal gave some valuable information respecting the green aloe as existing in Natal, Mexico and elsewhere :—

"The letter from Dr. Sutherland stated that the plant known by various names, had been established in this colony for years; it thrived in the coast districts. The leaves were smooth, the only spine or thorn on them being the solitary one at the tip. The seeds germinate on the parent stem, and strike their roots into the soil as soon as they fall. The leaves attain to their maximum growth in about six years, and are then from six to ten feet long. A full crop would yield probably 75 tons an acre. The yield of fibre is about two per cent an acre, thus yielding about 1½ tons of marketable fibre, varying according to demand and supply, in value, about £60. The fibre is known in commerce as 'Sisal Hemp,' and is exported abundantly from Mexico, the chief market is the United States; it is only of late attention has been drawn to it in Mauritius and St. Helena. The cost of working the machinery best adapted for separating the fibre from the cellular pulp and the other results have not, so far as he was aware, been determined on a thoroughly reliable basis. After numerous experiments with the plant conducted through a good many years, he came to the conclusion that sooner or later the fibre would figure largely in our exports. The great difficulty is machinery to work off large quantities. The hand scraping process applied in Mexico is too degrading for the progressive communities of our colonies. He tried the effect of steam with a pressure of 60 lb. to the inch, and believed he had succeeded; but his process slightly discoloured the fibre, which naturally is a pure white. Notwithstanding the creamy tinge the heat and moisture imparted, he sent some of the samples to London, and they were valued at £40 a ton, while the pure white hand-scraped samples were valued at £50 and ranked with the 'Sisal Hemp' prepared from the same aloe in Central America. He looked forward to valuable results to agriculture, when by means of machinery thousands of acres could be cleared with the facilities at present applicable to sugar cane. The plant grows best in good soil, taking up a fair share of moisture, but it would, grow luxuriantly in dry sandy soil. There are, however, other fibre yielding plants which merit atten-

tion, and will ere long become great factors in our industries : China grass, indigenous as well as exotic ; hemp, indigenous or crossed with Belgian ; Adam's needle, which yields 4 per cent of excellent fibre, New Zealand flax and several species of a native Hibiscus are ready to yield profitable returns to the demands of intelligent agriculture."

With this information before them, our planting readers can judge of the advisability of trying experiments with aloe culture. If the pulp can be separated from the fibre by chemical solutions without injury to the colour or strength of the fibre, and if the chemicals can be cheaply obtained, then the enterprize may be very profitable.

A copy of the Mauritius pamphlet reached us some time ago, but the member of our staff who had the task of translating it, was compelled to take a health trip before his task could be completed. A gentleman, C. S., who has just received a copy sends us a summary, which will be found elsewhere, as well as the remarks of a correspondent on aloes in the Northern Province.

CEYLON CINNAMON AND CHINA "CASSIA"

For a couple of centuries including the period of Dutch rule and the first half century of British rule, an average of about half a million lb. of cinnamon,—the fine spice of which Ceylon has a natural monopoly, sufficed for the wants of the world. The quantity exported was, indeed rather under the round half million, for the average for the five years ended 1841 was only 452,000 lb. In those early days, consumption was no doubt restricted by the enormous export duties which prevailed, and which, apart from increasing the competition of China cassia, tended to encourage the cultivation of the true cinnamon in Java and at Tellicherry on the west coast of India. At the end of the period mentioned Government had abolished the unprofitable cinnamon department, sold their gardens and gradually lowered the duties, which were finally abolished. The result was that the averages rose as follows :—

Five years ended 1846	...	lb. 530,000
,, 1851	...	,, 565,000
1856	...	,, 755,000
1861	...	,, 807,000
1866	...	,, 825,000

Then came the great spring, owing to what at the time was deemed the grand discovery, that it would pay better to send cinnamon chips into the market than distil cinnamon oil from them. In 1867 the million of pounds was, for the first time in history exceeded and in 1869 we had the culminating export of 2,685,000 lb. Next year the two millions were exceeded, but there was then a considerable decrease and the average for the five years ended 1871 was 1,834 000 lb. The average for the next five years went down to 1,264,000 lb ; and the two millions of pounds have not again been so closely approached since 1871 as in the season just closed, for which the exports, were :—

Baled cinnamon	...	lb. 1,600,000
Chips ...	...	,, 394,000
	Total	lb...1,994,000

For ten seasons there has been no higher export of baled bark than in that just closed, and the quantity of chips was only exceeded in 1879-80 when the enormous quantity of 474,484 lb. were shipped, or above the old average for total export. Recently there has been an agitation in favour of discontinuing the export of chips, so as to improve the prices of the fine, long-quilled cinnamon. Looking at the motives which usually actuate human nature, it is in the last degree improbable that any compact binding owners of cinnamon gardens not to export chips, or sell them for purposes of export, would be observed. A certain number will refuse to enter into the compact and another uncertain number, (we fear a considerable per centage) will violate it, either by directly exporting chips, or selling to those who will export. With the abolition of the duties, and the export of chips from Ceylon the cinnamon enterprize, both in Java and Western India, ceased to be profitable, although curiously enough, the growers of cassia in China believe that they are suffering from the competition of Java cinnamon. Although Ceylon has no monopoly of the growth of cinnamon, yet for fineness of quality its spice, largely grown in almost purely silicious sand, is entirely unequalled. But as in the case of coffee, the millions look to cheapness more than quality, and so the true cinnamon has long had a formidable rival in the cassia of China, the bark of an inferior variety of the cinnamon laurel, or, which at any rate as grown in China yields an inferior bark. How formidable that rival is, and how slight the effect on the market of withholding the chips, if that were possible, would be, we had no idea until we saw the statistics embodied in a report on China cassia by the Hong Kong Botanist. This report, which has been sent to us by the local Government for perusal, will be duly noticed. For the present we confine ourselves to the figures for exports from Canton. If these can be depended on the quantity of "Lignea, twigs and broken twigs" exported in 1879 considerably exceeded 100,000 piculs of 133⅓ lb. each,—say 13⅓ millions of pounds ! That, to be sure, was the maximum, but after a considerable falling-off in 1880 the exports in 1881 reached in piculs,

Lignea	...	54,526
Broken do.	...	3,129
Twigs	...	6,941
Bark of do.	...	2,832
Total piculs	...	67,428

or close on nine millions of lb. The average export of cassia, therefore, considerably exceeds four times, is, indeed about five-fold the figures for Ceylon cinnamon, and the Chinese growers would be only too ready to fill in the deficiency of supply created by the withholding of Ceylon chips. No doubt our most inferior chips are better in quality that the best China cassia. We recollect that some time about 1848, we received specimens of the China spice from the late Capt. Margesson, R. A. who was then serving at HongKong and who was interested in Ceylon cinnamon. The bark was coarse and pungently hot, instead of having the fine delicate flavour of our best quality ; but the very strength of "cassia," will be counted a merit by many of the pudding eaters of England. Besides bark, about an average of 2,000 piculs, or over a quarter of a million pounds of "cassia buds" are annually exported. Can anyreader tell us why the buds of our true cinnamon have never been exported as a spice from Ceylon? The source of the China cassia is now ascertained to be *exclusively* a variety of the true cinnamon, *cinnamonum cassia*, BLUME ; "yuk quai she" of the Chinese.

This has been conclusively settled, by the Hong-Kong botanist, as we shall subsequently shew. [See further on.]

THE NORTH-CENTRAL AND WANNI DISTRICTS OF CEYLON:

FIBRES WORTH £40 A TON AVAILABLE FOR PREPARATION.

(Communicated.)

A number of indigenous fibre-producing plants are to be found in the jungles of the Wanni, and among them is one specially prized by the natives for the strength and durability of its fibre. It is called "erukullai" (எருக்கிலை) in Tamil, and Wára (වැර) in Sinhalese, and grows prolifically in open grounds such as abandoned chenas and paddy fields. A sample sent to England recently was valued in London by a manufacturing firm at £40 per ton. In the last number of the *Tropical Agriculturist* (Oct. 2nd) page 332, a description is given of a fibre machine patented by Messrs. Dennis and Angell of America, which would just suit this plant. It would pay anyone to buy one of these portable machines and travel about the country fixing himself in a locality where the plant grew in abundance, and moving on to new ground when the stock became exhausted. The life would be a pleasant one, for he would in this way travel all over the country with constant change of scenery and climate, and, if of a botanical turn, would discover other plants of commercial value. The cost would be very little, as he would not have to invest in land nor keep up cultivation. The experiment is worth trying with any one who has a little money and time to spare.

What are our men of capital doing that they should allow 500 sturdy Sinhalese to leave their country without finding any means of employment for them here, and will they allow the wily Queenslander to take the wind out of their sails in this manner? Are there not rich lands in the North and North-Central Provinces to be bought where the Sinhalese could be employed among his own people and at a work which he thoroughly understands, viz., paddy cultivation. He would be ruled by a Government thoroughly acquainted with his laws and customs and ready to grant him such concessions as lies in its power, should he wish to purchase land. This subject is worthy the attention of all local agricultural Associations.

The immigrant road from Mannar to its junction with the central road at Madawachchi, would be a good base to work from and to commence the march of civilization over a country abounding with the remains of "ancient tanks, by the aid of which a dense population was enabled to live on plains now covered with forest and jungle where men go to hunt." A number of old tanks are to be found near the road, the first 20 miles from Madawachchi. There are telegraph stations at Mannar and Anuradhapura, and the tappal from Vavuuia-Vilankulum to Mannar runs along a good portion of it. If local labour is not available, coast coolies passing and repassing can be engaged in any number.

COFFEE AND WEEDS.

From the direction which public opinion is taking, we are quite prepared to hear some of these days that weeds—against which Mr. D. Morris and other experts so earnestly warned us as affording a nidus to the spores of *Hemileia vastatrix*—had they been allowed to grow at their own sweet will, would have saved us from the plague! We take from the *Madras Mail* two letters, one by the scientific agriculturist, Mr. Harman, the other by a Wynaad planter of seventeen years' experience. Mr. Harman shews how clean weeding deprives the soil not only of its nitrogen but of its moisture-absorbing power. The Wynaad planter is equally emphatic in decrying weeding as helping wash to carry away the soil, and he proceeds to curse drainage as art and part in the destructive process. Now we suppose no one will deny that, if weeds were not harmful otherwise, they would really be useful in binding the soil so as to resist wash. But they, especially grasses, would also bind or occupy the soil, so as to prevent, considerably, the spread of the feeding rootlets of the plant, which are near the surface. "If weeds do not enrich the soil," exclaims the planter, "what is the good of a fallow?" But a fallow between annual or temporary crops, the fallow being followed by careful ploughing and harrowing before another crop is put into the ground, is surely a very different thing to allowing weeds occupy a soil in which stands a perennial crop-yielder, like coffee? With all the rich volcanic soil of Java, clean weeding is now resorted to on government as well as private estates, where the labour supply renders such weeding possible, and, if weeds are allowed to grow amongst tea in India they are regularly hoed into the soil and amongst them is rarely to be found the *ageratum* which takes out of the soil exactly the same elements as the coffee tree requires. Both in India and Java, where terracing is resorted to, the weeds, if not deeply buried in the earth, are relegated to the outside edges of the terraces which they help to bind. But in both countries the soil is better capable of supporting a cultivated plant plus weeds, than is ours in Ceylon. "If they are not permitted to seed," writes Mr. Harman, and we agree with him that could the white weed and others be regularly turned over into the soil in their green state and before seeds had formed, the whole question would assume a different aspect. It would, certainly, be better that the weeds should rot *in situ* than that they should be carried to compost heaps and back again. But, unfortunately, white weed, or goat weed, or ageratum, or, as the Sinhalese call it, the weed of the wind, is, often, scarcely above ground when it begins to seed profusely; and while the scientists tell us to burn the fallen leaves, or to bury them with lime, if we want to get rid of the fungus, and we are compelled to reply that we cannot afford the cost: there is not much use in telling us that we must, some half-dozen times in the year, hoe the weeds into our soil instead of removing them. If we let them alone for even six months, the signals of distress thrown out by the coffee bushes soon tell us of the mischief done. Whatever may be the case, in Java and India, most of our Ceylon soils, we repeat, are too poor to support weeds, plus coffee. But while the question of weeds may be a debateable one, we scarcely thought that of drainage was. The old Wynaad planter, however, regards drainage as only second to clean weeding in the suicidal category. Unfortunately a large portion of our plantations are situated on the sides of hills so steep, that the frequent hoeing down system could not be attempted even if we could afford the labour and the money. We are ready to receive light, however, and we should be glad to learn the results of any experiments which have been tried in Ceylon in the direction of hoeing weeds into the soil periodically, instead of removing them and of either abstaining from drainage or allowing drains to choke up. During these hard times the experiment of allowing weeds to grow and drains to fill up must be in many cases involuntary. Our impression, how-

ever, is that although manuring has been intermitted, careful weeding is, whenever possible, still insisted on? Mr. Harman is now, we believe, on a visit to Ceylon, and may, perhaps enforce or modify his unorthodox views, after seeing our plantations.

WEEDS ON COFFEE ESTATES.

TO THE EDITOR OF THE "MADRAS MAIL."

SIR,—In your issue of the 16th inst. your correspondent "R.M.S.B.," commenting on the subject of sickling weeds in the monsoon on coffee estates, says: "It is surely obvious to the most casual observer that the coffee plants ought to have all the soil to themselves, and that whatever is abstracted from the soil by other vegetation is so much waste of power." To *casual* observers probably this is so, but by many a very different conclusion is arrived at by more thorough observation. To me it appears clear that a system of covering the soil by plants which prevent the evil effects of mechanical wash and the loss of nitrogen, which has recently been so conclusively proved by my old friend Mr. Warington at Rothamsted, and the increase of humus, so valuable an agent in absorbing and retaining moisture in the dry season, must require very strong arguments against it. The effect of weeds in binding the soil together and preventing the roots of the coffee tree from penetrating is not in my experience supported by fact. Nothing gives me greater pleasure at the close of the monsoon than to have a sufficiency of weeds in the soil to allow of the coolies fork turning over big clods to receive the ameliorating action of the air during the dry months; while the tap root of the coffee cares no more for surface weeds than do the roots of an oak. The rootlets of the coffee are of course in a measure broken by a deep forking, but not to the injury of the tree As to impoverishing the soil, I hold that weeds, if kept properly in hand—that is if they are not permitted to seed and are dug over annually—have exactly the opposite effect. On an estate I visited some years ago in Mysore, where clean weeding was attempted, the organic matter and water of combination had become reduced from 27·60 to 20·00 after ten years' cultivation; in other words the soil had lost 25 per cent of its power to absorb water from the air, equivalent roughly in a well cultivated soil to a fall of 10 inches of rain. There is also a great chemical loss in the absence of weeds continually rotting in the soil, there being less carbonic acid to assist the decomposition of silicates. If our weeds caused a permanent loss to the soil, I could understand there being an objection to their growth, but as they sooner or later pay back all they have borrowed as well as a handsome interest acquired from the air, I cannot endorse the deep-rooted prejudice in your correspondent's mind to their growth. In conclusion I quite agree with him that water should pass through the soil and not over it, but it would be interesting to the managers of the Ouchterlony valley estates to know how a profitable system of sub-soil drainage could be practically carried out over their extended cultivated area.

F. E. HARMAN, M. R. A. C., F. C. S.

II.

SIR,—A correspondent in your impression of the 15th instant seeks to revive the ancient fallacy that clean weeding is the proper system to follow on coffee estates. I thought this idea had been exploded long ago. The stock arguments of the binding of the soil and impoverishing it are again trotted out. The weeds certainly do bind the soil, and without their conservative action there would be very little soil left to bind on most estates after a couple of monsoons like the one we have lately passed through. So far from impoverishing the soil, vegetable growth of any kind, if buried, can only enrich it. Where the weeds are pulled up, carefully put in a bag, carried to the nearest road and burned—as I have seen done years ago—the soil certainly is impoverished; but where the weeds are allowed to grow in the wet weather, and are turned into the soil before the dry season sets in, we are simply continuing the natural system by which all rich soils have been formed—the decay of vegetable matter. In most books on coffee cultivation, marvellous plans are given for making compost heaps, the bases of all of which are rotted weeds. What difference is there between applying your weeds direct, and stacking them to be afterwards carried out and applied? If weeds do not enrich the soil, what is the meaning of a fallow? The notion that weeds impoverish the soil has been brought out by the so-called "practical" men, whose chief experience before their arrival in the coffee districts has been in the forcing of crops on the worn out garden soils of England, where it is only by manuring highly that crops can be produced at all. In such soil every weed that springs up is fattening on the manure put down for the forcing of the legitimate crop, and is rightly looked on as a bane. In garden cultivation the whole ground is occupied by the plants put down, of whatever nature they may be; no returning of weeds to the ground is possible, as before they could decompose into vegetable mould, the garden produce would be uprooted, and the ground cleaned for the sowing of a fresh crop. The state of affairs obtaining on a coffee estate is entirely different to this, and the tactics of the cabbage garden become wholly unsuitable. The *tree* is permanent, and each growth of weeds, as it is buried, is a gain to it. Not only do we return to the soil what was taken from it, but all that the weed also absorbed from the atmosphere, which is given by the most modern authorities as three-forths of the whole. "R. M. S. B." recommends draining. Perhaps he has tried it? I did so (to the cost of my employer) about 17 years ago, under the direction of the most experienced planter at that time in Wynaad. Two seasons were sufficient for us. If any of your readers are dissatisfied with the rate at which their soil is being naturally washed into the ravines let them try "catch draining."

Manantoddy. AGERATUM.

GRASS ON COFFEE ESTATES.

SIR,—The letters that have appeared lately in connection with a description of the weeding in the Ouchterlony Valley, make no distiction between grass and weeds The latter if kept low and thin do not do much harm; but grass cultivated as it is under that system of sickling down for several months in the year until there is a strong turf, and then plastering it over with earth can only have one effect on coffee, that is, cause it to disappear, and manuring does not even go as far as to repair the wear and tear under this system alone. Of course soil like the 'Valley' will stand it the longest, but I remember seeing some of the old coffee three years ago, that showed unmistakeable signs of the effects of

GHERKA HOOLOO.

ON TEA CULTIVATION.

A correspondent of the *Indian Tea Gazette*, asks a few questions on tea cultivation, viz:—1st—Does throwing the earth up round the stem of a tea bush do any good? 2nd.—Whether is it good, bad, or indifferent cultivation to hoe deep during the rains? 3rd.—Whether is it better to let weeds grow, and then hoe them into the ground, or not to let them grow at all.

It thus appears that even in Indian Tea Cultivation it is not yet settled whether it is better to bury than to remove weeds.

ADULTERATED TEA.—To test whether tea is coloured by carbonate of soda, put two tablespoonfuls of liquid ammonia, and half that of water in a corked bottle; put into this one tablespoonful of leaves; shake the bottle, and if a blue colour appears there is copper in the tea, and it is adulterated. *Journal of Design and Work.*

COCOA: ZULULAND WATTEGAMA, 5th Oct.—I send you a cocoa leaf by train today, which measures over 2 ft. long. I am not sure whether you have yet had one so large but if not just mention it in your paper to let people know that we can produce foliage as well as fruit in this part of the world. The tree is just 18 months old. [The leaf is simply magnificent. —ED.]

TEA SALES.—A Correspondent writes :—"Perhaps you may have noticed that in the last sale of Windsor Forest tea one chest broken pekoe was marked Windsor Forest G H D E, and sold for only 1/4, whereas what was marked Windsor Forest estates sold for 1/8. Now, I happen to know that one chest was packed at the same time as the other 12, and had been bulked with the rest; only as it was intended to be taken by a private individual, it was marked with the old Windsor Forest mark. However, it seems that it was put up for sale in the Lane, and being alone was not deemed as good as if it had made the 13th chest, and bene marked differently. Of course it is well-known one chest won't sell as well as a large number; still, whoever bought the one chest got the same tea 4d cheaper. I see there was a chest pekoe as well G. H. D. E. sold 1/2, W. F. division selling at 1/3¾."

ALOE FIBRE.—Messrs. Cantwell & Co. write as follows to a contemporary :—"The following will no doubt be found interesting to land-owners and cultivators. In November last we observed a quantity of prunings of the American aloe plant, together with other weeds, thrown at one of the gates of Government House for the purpose of being removed as refuse. We procured some of the aloe plant leaves, many of which were over six feet in length, and subjected them to our patent process for extraction of the fibre. A sample of the fibre taken from them was sent to London and by the last Mail advice was received valuing it at £28 per ton, and offering to take any quantity of it at that price. The advice also stated that the highest price that any aloe fibre has hitherto realized in the London market was £16 per ton, so that the Indian sample is nearly double the value of that at present obtainable in the market. Land stocked with plants of the foregoing description would probably yield about 50 maunds of fibre per beegah annually. The cost of cultivation would be very little, as the plant will grow almost anywhere and requires no attention. The cost of preparing the fibre by our process, which is very simple and adapted to the circumstances of the ryot, would not exceed eight annas per maund. Even allowing that the cost of production and placing the material on the Calcutta market would be R2 per maund and the price obtained for it only R8 per maund, the difference, R6 per maund, would give a net profit of R300 per beegah, which is worthy the serious attention of cultivators. Every ryot should at least have his fences and hedgerows stocked with a good description of the American Aloe plant."—*Indian Agriculturist.* ["A good description of the American aloe"? The only American aloe we know of in Ceylon is the grey, comparatively slow-growing *agave americana.* The green aloe, *fourcroya gigantea,* grows much more rapidly and luxuriantly, but the fibres of its leaves may be weaker? What we want to know is the best species or variety of the aloe to cultivate for the production of "hemp," and we have at last obtained the information which will be given in Monday's paper.—ED.]

ENEMIES OF TEA.—Yattiyantota, 7th Oct.—I am sending by this post a matchbox containing some small green poochies which I find infesting the young shoots of newly pruned tea. The shoots are also badly affected with blackbug. Have the pootchies come to feed on the shoots or on the bug? [The green poochies are the larvæ of a genus of flies belonging to the family Syrphidæ. They somewhat resemble small wasps, and in their larvæ state feed upon aphides &c. The larvæ received from our correspondent, were no doubt feeding on the young and tender black bug at the time of their capture, unless they happened to be within reach of aphides, their usual food, of which they devour immense numbers. Since they have been in our possession, many of them have turned into the perfect insect, and thus we have been able to identify them.—11th Oct. 1882.]

COFFEE PLANTING DEPRESSION AND THE CAUSE. W. F. L. writes :—"I cannot understand 'W.'s letters. Such districts as Pundaloya, Rambodda, Kalebokka, Rangalla, and the best parts of the new districts would not have gone out as they have done without leaf disease. It is leaf-disease absolutely that has reduced their crops to almost nil. The Governor's remark, in his opening Speech in Council, speaking of the falling-off of coffee crops as being owing to the falling-off of manuring, is logically 'the cart before the horse.' Planters manured as long as they could, and only stopped when the coffee *with* manure ceased to pay for its continuance. When estimates would admit of it no longer, they were perforce obliged to stop. Would that Lunatic Asylums could be stopped also, and that felons' Prisons were a little less inviting, and we might then keep more of our own property."

NEW PRODUCTS IN THE HILL COUNTRY.—*Rubber trees* in Doombera are beginning to assume quite an altered shape and appearance. Instead of the branches growing upwards, they seem, after the second year, to bend over and hang down to the ground, something like what is known in coffee planting as an umbrella tree. The tree thus loses in height, but gains in breadth, and the branches quite conceal the stem. *Cardamoms,*—I hear of some cardamom stools in Dolosbagie giving 1 to 1½ lb. per stool of dry ripe fruit. *Cocoa.*—It is generally believed that a cocoa plant is ruined if its tap-root is cut. I know one instance where a large number were regularly cut, and so far as one can see, without any evil consequences. On an estate in Nilambe, where all efforts to grow the ordinary Doombera cocoa have been most disappointing, the Caraccas variety is flourishing. Maravilla cocoa, or what has been imported in one instance as such, almost invariably splits up into five leading primaries about four feet above the ground. The pods are green.—"Times."

INDIA-RUBBER AND CINCHONA IN GUAYAQUIL.—In a Consular Report recently issued on the trade and commerce of Ecuador through the port of Guayaquil during the year 1881, it is stated that the amount of indiarubber collected during the year exceeded that shipped in 1880 by about 10 per cent. Up to the present no measures have been taken by the Government to prevent the cutting down of the trees producing this article, and this practice is slowly destroying the resources of the country in this respect. Under the head of Peruvian Bark we are informed that the sudden fall in the price of this article in Europe considerably curtailed the exportation, which would otherwise have been in excess of 1880. As it is, there is a small decrease noticeable, from the fact that most of the inferior grades of bark which had been collected were retained in Ecuador, the owners fearing that the expenses of conveyance would consume even more than the proceeds of the bark in Europe. New districts containing large forests of the best quality of bark-yielding trees have been recently discovered in the interior.—*Gardeners' Chronicle.*

Correspondence.

To the Editor of the Ceylon Observer.

CEARA RUBBER.

DEAR SIR,—In your "overland" edition just arrived, there is an interesting correspondence started by Mr. Thiselton Dyer, respecting the ceara rubber which he sent to Mr. Silver to test. As you have Dr. Trimen close at hand, could you not, for the information of the public in this country and for planters in Ceylon, find out from him what the difference was between No. 1 and the No. 2 rubber he gave to Mr. T. Dyer. We all know that any rubber that is sent home that is sticky and will not congeal properly (even in this cold climate) is of very small value, whereas one sample that came home was beautifully dry and hard and valued at 3s 9d per lb.

Another thing must be borne in mind in the India-rubber trade, viz., the prices fluctuate in certain seasons of the year. This is caused by speculators who get up the prices and then make sales for goods to arrive, so that they can come in again at a low price.
—Yours truly, THOS. CHRISTY.

[Dr. Trimen could not explain the difference between the samples, beyond that the one may have been less carefully collected than the other and had probably foreign matter, dust, &c., mixed with the rubber.—ED.]

COFFEE AND PEPPER EXPORTS FROM WESTERN INDIA.

Tellicherry, 26th September 1882.

DEAR SIR,—Along with this we have the pleasure to hand you a statement of our exports of coffee and pepper for the year ending 30th June last. This also includes similar exports from the other ports on this coast. From this you will observe that the crop of coffee has been an improvement on the previous one, but pepper shows a deficiency. The crop of Mysore native coffee was below the average, both in quantity and quality, and we fear the extensive introduction of Coorg plants there must gradually alter the character of this produce.

The course of prices of both coffee and pepper followed closely that of Europe. In fact, the keenness of merchants to do business, either for a very small commission or on speculation, kept rates far too near those ruling in Europe to allow of anything like a fair profit.

The pepper market was also influenced by the demand from Indian ports, with which a large business was done through native agency, and during the latter part of 1881 especially, few if any transactions took place on European account.

The coming crop of coffee is expected to be a fair one though somewhat below the last. The south-west monsoon has been unprecedentedly heavy, and the estates on the Ghauts have suffered from the excessive rainfall and high winds. Estates situated to the eastward of the Ghauts, however, such as those in the Bamboo district of Coorg, have suffered but little as far as crop is concerned and benefited by the suitableness of the weather for planting. In the Eastern Mysore districts reports are, however, not very favorable.

We have not been able to obtain very reliable information about the pepper crop, but believe it will not be equal to the last. The cultivation is entirely in native hands, so it is most difficult to get information that can be safely depended on.—We are, dear sir, yours faithfully, ALSTONS & Co.

LANTANA-INFESTED LAND RE-CULTIVATED WITH COFFEE.

DEAR SIR,—With reference to your article on lantana in last night's *Observer*, the estate of Attabagey, on the right-hand side of the road between Gampola and Pussellawa, is a case in point.

It had been originally chena, was planted up by Mr. Frank Sabonadiere with coffee, gave one good, and two or three indifferent, crops of coffee, and was

allowed to "snuff out." It was soon covered with lantana, and I remember Mr. F. Sabonadiere telling me that he believed the land would be rendered fit for growing coffee in 7 or 8 years. This was 17 years ago; the land has been planted up about two years. So it was allowed to lie fallow for 15 years. What the result of the planting up may be, I do not know.—Yours truly, X.

NEW PRODUCTS IN DUMBARA FELIX!

Dumbara, 9th Oct. 1882.

DEAR SIR,—I have been knocking about in this district for a few days, and think you might like to hear the impressions of a casual visitor.

Cocoa, as of course you know, is A 1. I must confess though that, high as my expectations were, they have been far supassed by the reality. I have seen it at all ages, from the seedling of a few inches to the patriarch of twenty years old and more than as many feet, and the strongest impression they have left on my mind is *crop*, though I have been informed that this is the smallest crop of the two. I have seen trees from four to five years old, with 100 to 120 pods on them beyond the doubtful age; this represents eight to ten cwts. an acre. And this is their small crop!

Liberian comes only second to cocoa, and a very good second it seems too. I have seen a five acre clearing, four and a bittock, where some trees are bearing at the rate of twenty-four cwt. per acre (ascertained by counting the berries), and the average of the whole clearing cannot be under fifteen cwt Again am I told that this is "our small crop"! Three years old trees with 650 berries, or four cwt. an acre. Leaf disease makes hardly any impression on it, but it shows signs of drought more readily than the Arabian variety.

The old staple (Coffee) too shows more crop generally than I have seen anywhere this year: on one place in particular, where a lot of soft wood shade trees have been ringed out, there must be a crop of five cwt an acre at least—not bad for this year. Alongside of this there is a very fine clearing of cocoa, Liberian and ceara rubber, with tobacco planted between the rows, and all coming on as well as could be wished. This latter is a step anyhow towards carrying out your suggestion, of planting something to preserve the nitrates, though I fear tobacco will take more out of the soil than it puts in. Happy Dumbara!—Yours faithfully, HULLIGAN GUARD.

P. S.—Touching this same preservation of nitrates, would rape or clover grow so low down as this? Mustard does, I know, as I have often seen it in chenas. And do you think an equally good effect would be produced by simply grass-knifing the plants, and leaving them to rot on the surface, giving the place a dig over say once a year; as I fear few estates could afford to dig over as often as the plants came into seed?

[Tobacco, which is removed from the soil and not turned down into it, is one of the most exhausting of crops, depriving the soil especially of potash. Tobacco culture involves heavy manuring or speedy impoverishment of the soil. On the subject of weeds, see our remarks in today's issue on the letters of Mr. Harman and a Wynaad planter. We do not suppose clover would succeed in the hot dry climate of Dumbara. —ED.]

ALOE CULTIVATION.

Colombo, 10th Oct. 1882.

DEAR SIR,—I have once or twice directed your attention to the increasing cultivation of aloes and the manufacture of hemp therefrom in the* Mauritius, and pointed out how suited the soil, climate and circumstances of this island are for the same purposes.

Application having been made to a firm in Mauritius for information as to the description of aloes cultivated and the method of manufacture, I have been obligingly furnished with full particulars not only as to the mode of cultivation, but as to the description of the machinery employed in the manufacture of the hemp.

The description of aloes cultivated in Mauritius is the *Fourcroya gigantea*, or *Agave fœtida*. It appears to grow within the tropics in almost any sort of soil, in the most exhausted to the richest, as well in the lowcountry as in the high, in a dry climate as in a moist one; and when it is once planted does not require much cultivation. I wrote to the Director of the Royal Botanical Gardens at Peradeniya to enquire whether this description of *Agave* is the same which grows so well in the higher districts of Ceylon, and, though he has not favoured me with a reply, I am satisfied that it is.

In Mauritius it is propagated either by seeds planted at stake or by means of young plants from twelve months to three years old: they are put in the ground five feet apart.

If grown from seed, they require five years to attain their full size, but, if plants 18 inches high are put in, they mature in three years.

On an average they blossom in seven or eight years; they can therefore be cut only four or five times before requiring to be re-planted.

The yield of clean fibre with the improved machine is three per cent of the green leaf, or equal to a ton to a ton and-a-half of fibre per acre.

The machinery is very simple and inexpensive.* The value of the hemp was at first £30 to £32 per ton in London; it advanced subsequently to £38 to £40 owing to the high price of Manilla hemp. The Mauritius firm say that the latest accounts from England are not so favourable, and in some quarters it is feared the supply of fibre from that island alone will exceed what is required for the purposes for which it serves.

Be that as it may, the cultivation of a product which costs so little to grow and whose area of growth is so enormous, is not likely to be stopped by dismal forebodings, so long as the immediate prospects are highly favourable, and the question will as a matter of course ultimately resolve itself into the cost of labour and transport. There are hundreds of thousands of acres of land in Ceylon adapted to its cultivation, with the probability of a maximum yield per acre, owing to the humidity of the climate. It would be a cultivation adapted to the genius of the Sinhalese, if they could find at central factories markets for their green leaves.—Yours truly, C. S.

ALOE FIBRE: A "GRATTEUSE" NOT TO COST MORE THAN R200. CULTIVATION AND PREPARATION IN CEYLON.

Colombo, 11th Oct. 1882.

DEAR SIR,—Referring to my letter of yesterday, will you allow me to explain that, in describing the machinery used in the manufacture of hemp in Mauritius as being very simple and inexpensive, I did not include the cost of the motive power, because its existence in Ceylon was one of the circumstances which made the island, in my opinion, as suited to the cultivation of aloes as Mauritius?

If the previous possession of steam engines on the sugar estates made the cultivation of the aloes practicable in the Mauritius, does not our water and steam-power place us in an equally favorable position? In

* Protest after protest against the definite article, seems in vain. Why *the* Mauritius and not the Ceylon?—ED.

* See our article and extracts: can machinery costing £1,000 at least be called inexpensive.—ED.

saying the machinery was simple and inexpensive, I was referring to the "Gratteuse" only. I am almost certain that either Messrs. John Walker & Co., or the Fairfield Iron Works would make a "Gratteuse" and attach it to the water-power on our coffee estates, or the steam-power in Colombo, or elsewhere, for the sum of R200;—nay, more, I believe any intelligent superintendent of a coffee estate could convert an old-fashioned coffee pulper into a "gratteuse" for R20. The fact is, the machine is simply a modification of the coir fibre machine introduced here by the late David Wilson and myself, nearly a quarter of a century ago.

Instead of the steel combing pins, pieces of 2 inch angle iron are screwed across the drum at regular distances, and these are the scrapers. The thick end of the green leaf is introduced between the rollers, and the drum furnished with scrapers driven at great speed, scrape off the epidermis and pulp of one side of the leaf, which, when finished, has to be withdrawn to present the other side. In the coir machines there is nothing to support the husk against the combing pins, but in the "Gratteuse" an adjustable sloping breast or chop, placed a little below the periphery of the drum, supports the aloe leaf against the scrapers. This breast is three-quarters of an inch thick, and is sloped off exactly like the end of the inner side of a thumb. On this surface the leaf is apparently scraped, the chops being adjusted as close as experience dictates, to the scrapers. There are 18 scrapers to each drum placed at regular distances.

The defect of the machine which Monsieur Chazal describes as "brutal" is that it only scrapes one side of the leaf at a time.

There is on our coffee estates, and in Colombo and other places, water, and steam power, to drive several thousand Gratteuses. At the coffee stores in Slave Island, I worked twenty-four coir machines with the engine which drove the peeler and sizers: these which were purchased by Mr. de Soysa, and those on the Horrekella estate, were the only ones, that could be used in the Island, until our patent expired. At Horrekella 60,000 plantlings have been put in, and many more will no doubt be added. Five years hence, if not long before then, the coir fibre machines will probably be converted into Gratteuses, if in, the meantime some better method of separating the fibre from the pulp is not discovered.

If the natives can be induced to plant aloes, the mills in Colombo, could be supplied with leaves from a radius of twenty or thirty miles owing to the cheapness of transport, as instanced in the case of firewood.

In addition to the steam-power, Colombo possesses baling power, capable of pressing a thousand bales of three hundred pounds each per diem. I may be excused therefore, for not including cost of power and buildings in calculating the cost of the machinery. On coffee estates, the hemp could be manufactured even more cheaply than in Colombo, and sent here in bundles, as in the case of Cinchona twigs, to be baled and shipped. In addition to the profit on the manufacture of the fibre, there would be an enormous mass of pulp, which might or might not be converted into nitrogenous manure for the coffee. But alas! we should have to wait five years for this consummation, by which time according to the prediction of our prophet, coffee in Ceylon will be a thing of the past; he prophesied yesterday that if with favorable weather, we are blessed next year with a good coffee crop, as he thought possible, it would be our last! I admit that in uttering this prediction, he did so, jovially and laughingly, as if he disbelieved in the fulfilment of his own prophesy, and I am sure he intended to bless the enterprise, and not to curse it—so we may hope that even five years hence, there will be some coffee in existence which may be manured with the pulp of the "Fourcroya Gigantea" if it is not coverted into paper pulp, for the manufacture of tea boxes, which it probably will be.—Yours truly, C. S.

P. S.—I suspect our planters would find some way of using the leaves before they attained maturity, as in the case of cinchona trees. The maxim that half a loaf is better than no bread is a very favorite one in Ceylon just now.

PROLONGED VITALITY OF SEEDS.—In *Coulter's Gazette* it is recorded that seeds of Pyrus coronaria germinated after lying dormant for twenty-three years. If there was no mistake on the part of the observers, these seeds were buried beneath the foundation of a building erected in 1859, and pulled down last spring.—*Gardeners' Chronicle.*

TEA PESTS.—In the weather and tea crop reports of the Indian *Tea Gazette*, we find this ominous record:—"SYLHET.—Rainfall to date 107·80. Weather, favorable for manufacture. Flushes at present fair, but too much bunjee. Blight, blister blight, red spider, and beetle blight,—a little of each."

TEA IN KULU AND KANGRA.—The correspondent of the *Delhi Gazette* writes, September 22nd:—"I hear from the Kangra Valley that it has been a fairly average year for the planters; but at present the tea bushes are covered with an unusual and abnormal amount of seed. Besides its far greater rainfall, the Kangra Valley has this great advantage over Kulu in the matter of tea-growing; it lies parallel to the great snowy ranges, and is in a great measure sheltered from cold north winds; whilst the Kulu Valley, funnel-like, slopes gradually up to the snowy range, at right angles; and through the depression of the Rhotang pass, which may be considered the neck of the funnel, these cold north winds sweep down over the valley. I have at times seen the tea bushes so nipped by them that they looked as if they had been scorched. Lovely weather, with very cool nights and mornings. The high ranges are capped with snow; flights of wild fowl are passing down *en route* to the plains; those birds who winter in Kulu are beginning to put in an appearance; and there is every promise of abundant autumn crops."

NEW CINCHONA PREPARATION.—Some time ago the Secretary of State sent out to this Presidency, for trial, certain new preparations of cinchona, viz., *quinetum tartrate Cinchona Alkaloid*, and *Liquor Amorphous Sulphate* produced by Mr. Whiffen, the Quinine manufacturer, from bark sent from the Nilgiris. These were handed over to the Surgeon-General with the Government of Madras who supplied them to certain medical officers for trial and report. It appears from the reports of these officers that the *tartrate of quinetum* proved successful in nearly 91 per cent of the patients, while quinine had to be substituted in nearly 9 per cent of the cases, and only one death occurred; but it produced symptoms of nausea, giddiness, headache and vomiting in about 20 per cent of the cases. The *cinchona alkaloid* was tried with the following results:—Nearly 81 per cent recovered, and in 19 per cent of the cases quinine had to be resorted to, and no deaths occurred. The special symptoms noticed above were observed in 17·8 per cent of the patients. In the case of the *Liquor of amorphous sulphate of quinine*, it proved effectual in nearly 86 per cent and quinine had to be had recourse to in about 14 per cent of the subjects experimented upon; only one case succumbed, but as the patient had been in hospital only one day, the Surgeon-General, considers that it ought to be eliminated from the statistics. The Surgeon-General, however, we hear, is of opinion that the number of cases is too small to afford any valuable data as to the value of the preparations, and the Government agreeing with him have, we understand, directed that further trials be made with them and reported upon.—*Madras Times.*

COFFEE.—The French are said to consume four times, the Americans eight times, and the Germans twelve times, as much ceffee per head as the English. —*British Trade Journal.*

MALT COFFEE.—A patent has been published at the instance of Arthur Conroy and Michael Conroy, both of Liverpool, entitled "Improvements in the treatment of malt to produce an article of diet, which may be used as a substitute for coffee." Roasted ground coffee is exhausted with boiling water; with the extract thus formed, raw and roasted malt are saturated, and then dried. The result is a material closely resembling real coffee in taste and appearance, but possessing an invaluable property of the malt diastase, viz., that of causing starchy substances, such as bread, &c., to dissolve in the stomach, and in this way it materially assists digestion. It is, too, said to be more nutritious than ordinary ceffee, as the phosphates and albumineus matters of the malt remain in the mixture. —*Planters Gazette.*

HOW TO MAKE TEA.—Some remarks recently appeared in a trade journal on this subject. The writer says :—Fill the kettle with cold water from the cistern, boil quickly. When the water is at the boil, *not boiled*, pour into the teapot a little to heat it up, pour out and let the teapot dry; put in the tea in the dry pot, let it stand so for two minutes, then pour in the boiling water and draw ten minutes; use a little cream, sugar to taste, and you have a delicious cup of tea.

To give my reasons why this short date should be so, I give the analysis of a pound of fine Assam tea, taken from an authority in the trade:

	Ounces.	Grains.
Water	0 ...	350
Theine	0 ...	210
Caseine	2 ...	175
Aromatic Oil	0 ...	52
Gum	2 ...	385
Sugar	0 ...	211
Fat	0 ...	280
Tannic Acid	4 ...	87
Woody Fibre	3 ...	87
Mineral Matter ...	0 ...	350

Now, the volatile oil contained in tea is the component part which gives it flavour, and which, when long drawn evaporates. The theine or caseine contained in tea refreshes and gives repose, and assists digestion, while the tannin, of which there is a large proportion, is a powerful astringent. This tannin comes out when the tea is overdrawn. The theine and oil evaporate, and we have nothing but a bitter and unwholesome beverage which destroys digestion, excites the nerves, and hurts the health. The time was when twenty minutes was not too long to draw fine pure Congou; that was when China teas were alone consumed, and the manufacture was very different. Teas were so difficult to get to shipping ports, and the time thus employed was so long, that unless the tea was extremely well cured, well dried and tightly rolled before it had arrived at Canton it would have been unfit for shipment, but now with open ports all over China teas are rapidly and poorly cured, the manufactures knowing that when they commence to deteriorate they will be on the hands of the grocer. Hence it will be found that China teas and also Assams do not require the old-fashioned time to draw. This it would be well to remember, for what, after all, is tea? At best it is but a beverage; its nourishing properties are very few; it is rather more of a stimulant, and to make it enjoyable it should be made and used to create the greatest amount of happiness and pleasure. To do so every grocer should educate his customer. I would ask every grocer to try three experiments in tea making: 1st Make it as I have described; 2nd. Make it with boiled water and draw double my time; 3rd. Put in the same quantity in old boiled water that I have done with mine, and you will find it does not draw; then do as some wives do, add another spoonful of tea to bring up the strength and he will find a strong decoction.

COTTON SEED before the American civil war was supposed to be worthless, except for fertilizing purposes, the business of expressing the oil which it contains has now become a profitable business, which is indicated by the fact that there are 70 odd mills devoted to it. From each ton of seed is produced 35 gallons of oil, which can be sold at from 40 to 50 cents per gallon. Seven hundred and fifty pounds of oil cake likewise are obtained, worth $13. The hulls, worth $4, are disposed of as a part of the yield. For lubricating machinery, for grinding with white lead and mixing paints, and for salad dressing (in the guise of the product of the Spanish olive), cotton seed oil is in extensive use vegetable and animal oils also have an extensive rival in it.—*Rio News.*

PUTREFACTION AND ANTISEPTICS.—In the course of researches on this subject, M. Le Bon has lately obtained results which seem to have important practical bearings. The so-called "normal liquid" he used for putrefaction was an aqueous solution containing hashed meat to the extent of a tenth of its weight. He finds (1) that the disinfectant power of any antiseptic is weaker the older the putrefaction (new products are given off, in time, by the putrefying liquid, that are not so easily destroyed). (2) Measuring the power of antiseptics by their disinfactent properties on a given weight of the normal liquid, the strongest disinfectants appear to be (in order), permanganate of potash, chloride of lime, sulphate of iron acidified with acetic acid, carbolic acid, and the glycerobetates of sodium and potassium. (3) There is no parallelism between disinfectant action and action on microbes (or minute organism). Thus, permanganate of potash, so strong in the former respect, has no appreciable action on microbes; alcohol, a strong preventer of microbes, is very weak as a disinfectant. Nor (4) is there parallelism between the power of preventing putrefaction and that of stopping it when it has arisen. Alcohol and carbolic acid, preservative agents *par excellence*, have very little effect on putrefaction once commenced (5) With exception of a very small number of substances that are strong poisons (as bichloride of mercury), most antiseptics, and notably carbolic acid, have very little action on bacteria. M. Le Bon has at present carbolized solutions several months old, and rich in bacteria; indeed, he thinks, this acid one of the best liquids for preserving live bacteria a long time. (6) There is no parallelism between the virulent power of a substance in putrefaction and the toxical power of volatile compounds given off by it; indeed these properties seem to be even in inverse ratio. A frog is placed in an enclosure with some of the liquid. When putrefaction sets in, a very fetid odeur is produced, and the liquid swarms with bacteria, and is known to be very virulent if injected under the skin of an animal; but the frog merely breathing the effluvia, takes no harm. After two months the liquid ceases to have virulent properties, but the animal breathing its volatile products is killed. (7) The very small quantity of products of advanced putrefaction necessary to kill an animal by simple mixture with air proves these volatile alkaloids to be extremely poisoneus. M. Le Bon ascertained that they are so to man. He knows only a very small number of substances, such as nicotine, prussic acid, and the new alkaloid he lately extracted from tobacco, that are as poisonous. (8) The experiments explain the evils arising from bodies long buried, and prove that the atmosphere of cemeteries (contrary to what has been affirmed on the score of there being few microbes present), may be very dangerous. In connexion with typhoid fever, too, and other affections, the volatile alkaloids produced by action of microbes on certain organic substances, are doubtless largely active.—*London Times.*

COCA LEAF *vs.* KOLA NUT.—A Maskeliya planter enquired yesterday as to the "nut" which is used as a great stimulant by the American Indians or Africans. We mentioned in reply the coca (*erythroxylon coca*) but we should have corrected *nut* to *leaf*. The leaves of the coca are specially used as stimulants by the Peruvian Indians. Perhaps, though our correspondent meant the kola nut (*cola acuminata*), the seeds or nuts of which are used as a sort of condiment by the natives of tropical Africa.

CHARCOAL AND ITS USES.—Charcoal laid flat on a burn will cause the pain to abate; tainted meat, surrounded with it, is sweetened; strewn over heaps of decomposed pelts, or over dead animals, it prevents any unpleasant odour; foul water is purified by it; it sweetens offensive air if placed in shallow trays around apartments. It is so porous that it absorbs and condenses gases most rapidly. One cubic inch of fresh charcoal will absorb nearly 100 cubic inches of gaseous ammonia. Charcoal forms an unrivalled poultice for malignant wounds and sores. In cases of what is called "proud flesh" it is invaluable. It hurts no texture, injures no colour, and is a simple and safe sweetener and disinfectant.—*Queenslander.*

INSECTS AND TOBACCO JUICE: WORTH A TRIAL.—A suggestion (based on actual experiment has been made to the French Horticultural Society by M. Boizard, which is worth listening to and proving by all those who have conservatories and delight in them. If a solution of tobacco-juice is vapourized by boiling on a small fire until the liquid has disappeared, it will destroy every insect without harming the tenderest plant. The plants thus rid of insects are exempt from their attacks for six months, with the exception of aphides and thrips. The temperature of the hot-house should be as low as possible whilst the operation is going on. In the open air the tobacco vapour might be applied through a tube.

NEW REMEDIES.—A correspondent writes:—I enclose you some extracts from "A Record of New Remedies" (published by Burgoyne's), dated June 1882, which may possess some interest to many of your readers. I am aware you have often referred to the papaw, but cannot recollect it being mentioned as a remedy for tapeworm before, or for diphtheria. The notes on eucalyptus and bulby tree gum you will find interesting." The extracts are as follows:—

Papain.—The solnble ferment of carica papaya possesses remarkable properties of digesting animal substances, being in fact, a valnable pepsine. Tough meat is rendered tender and easy of digestion when boiled in water to which a small quantity of the juice has been added. Hard-boiled eggs soaked in the water are rendered soft and friable. In Quito the juice is used to smear over meat before cooking. In Java, Guiana, and the Mascerine islands, newly killed meat is wrapped in leaves of the tree to render it tender. Papayatine, the active principle, has been obtained frem the fruit, seeds, and milk of the tree, and is a white amorphous substance. As a vermifuge papain has proved successful, being very active in digesting and expelling *tapeworm*. Dr. Brnchut, of the Academy of Science of Paris, has experimented with the juice in diptheria, applied externally to the diphtheritic deposit, it dissoherit, and gives good hope of being a serviceable remedy in that disease.

Coconut (Remedy for tapeworm).—In the Antilles the coconut is a popnlar remedy in taenia.. Dr. Martiali, chief of the medical service in Bengal, reports that it is most efficacions A coconut is opened the meat removed, scraped, and three. hours after being administered a dose of caster oil is given, the success being most complete.

Alstonia Constricta, or Queensland feror bark, is in common nse in Australia as an antiperiodic. It has been nsed as a substitute for hops to make beer bitter, and as a domestic remedy for malarial fevers. It is sometimes called native quinine. Alstonia constricta contains several alkaloids, one of which, alstonidine, is said to combine the properties of quinine and nuxvonica.

Bulby Tree Gum.—This gum, the hardened juice of sapeta Mueller Bt., also known by the names of balata or tunoguna, or leche-de-popa, is coming into general use as a substitute for India-rubber and gutta-purcha. It scems to be an intermediary between caoutchonc and gutta-percha, and is being successfully employed in the manufacture of submarine cables and for other purposes. When properly prepared, the gum presents a white, dry and hard appearance.

THE QUESTION OF TEA CULTIVATION seems to be attracting more attention than ever in Ceylon. A suggestion is made that worn-out and abandoned coffee land should be planted with the hardy shrub, the cost of which would be comparatively small. The question of labour, upon which the depression in the coffee enterprize has acted so adversely, has, however, to be reckoned with. But, with the introduction of improved machinery, Ceylon quite expects to be able to compete with India in the tea industry.—*British Trade Journal.*

TROPICAL FRUITS AND VEGETABLES: JAMAICA WITH ITS FLOWER AND FRUITS NOW BEATING CEYLON.—We have been favoured by our occasional correspondent, Mr. J. Hart, Superintendent of the Cinchona Plantations at Gordon Town, Jamaica, withphotogra phs of a flower show held in Kingston, Jamaica, in June last, and of a group of tropical fruits and vegetables exhibited on that occasion. The latter we have had engraved, and now present it to our readers (fig. 58). The group, which was arranged by Mr. Hart, included in the centre a plant of the Calalu, Phytolacca icosandra, a common subject in the West Indian Islands; in front of it pine-apples and artichokes, and on the right bananas, mangoes (Mangifera indica), the fruit of the naseberry (Achras Sapota), Seville oranges, carrots, the coconut (Cocos nucifera), vegetable marrow, celery, turnips, plantains (Musa paradisiaca), and rice Oryza sativa). On the left are the jack fruit (Fruit Artocarpus intergrifolia), large beans, potatos, Indian corn, gourds, yams, Colocasia esculenta, pumpkins, cucumbers, cabbage, Muscat grapes, the mammee apple (Mammea americana), the Shaddock (Citrus decumana), and above these is a comb of honey. The exhibition on the whole appears to have been a great improvement on that of the previous year, and included a considerable number of plants of a decorative character, sent from the various public gardens, &c., under the supervision of Mr. D. Morris, and many admirably-grown specimen plants exhibited by residents in Kingston.—*Gardeners' Chronicle.*

DISEASES OF PLANTS.—It is proposed to form an international Association of those botanists and entomologists most competent to deal with this important subject, and for the purpose of studying the natural history of plant diseases, and the investigation of the means whereby they may be obviated or cured. The main objects proposed are:—1. Recognition and speedy communication of information as to the various forms of diseases of plants of all kinds, the spread of epidemics, and the prevention of the same. 2. The collection of statistics respecting diseases in various localities and observation of the influences of situation, soil, climate, &c. 3. Investigations as to the power of particular varieties to resist disturbing influences, and especially frost, and also the making of various cultural experiments with a view to discover the best varieties of plants to be cultivated in different localities. Co-operation of members in different countries is indispensable, and they should be chosen from among the most able men having sound knowledge of the variations, &c., of plants. Scientific investigation of new forms of plant diseases will be conducted both anatomically and chemically. For the furtherance of the object of the Society it is advisable to issue an appeal to the members, the appeal to take the form of questions and tables to be filled up with notes on the weather, and other remarks. The growth of seeds is also to be studied with regard to locality, climate, &c.: as also the cultivation of fruit, forest, and garden trees. The nature of the soil is to be taken into consideration, and the power of different plants to withstand weather, especially frost. Dr. Paul Sorauer, of Proskau, Silesia, is the secretary and originator of the proposed Society, and in each country special representatives are to be appointed to collect information.—*Planters' Gazette.*

ORANGE WINES.—A writer in the *Semi-Tropic California* describes his experience in making orange wines from the wild orange of Florida years ago. He says that it cannot be surpassed for medical purposes, and sold when only eight months old for $3 per gallon. The oranges must be perfectly ripe. Peel them and cut them in halves, crosswise of the cells; squeeze into a tub. The press used must be so close that the seeds cannot pass into the must. Add 2 lbs. of white sugar to each gallon of the sour orange juice, or 1 lb. to each gallon of sweet orange juice; and one quart of water to each gallon of the mixed sugar and juice. Close fermentation is necessary. The resultant wine is amber-coloured, and tastes like dry hock, with the orange aroma. Vinegar can be made from the refuse, and extract from the peels.—*Chemist and Druggist.*

AGRICULTURE IN CHINA.—The following estimate by the *North China Herald* of Chinese Agriculture will take most of our readers by suprise:—"From the time of Shen Nung, the Divine Husbandman, down to the present day, the pursuit of agriculture has always been held in high estimation by the Chinese. Next to the study of the priceless literary treasures bequeathed by the sages of old, the tilling of the Earth, the great 'Mother' of Chinese mythology, ranks in dignity and honour. It is difficult to say how many grains of superstition may be found in this time-honoured idea, or whether it takes its rise entirely from utilitarian considerations. It is also difficult to reconcile the great deference professed towards agricultural science in China with the very imperfect results that are produced. There is no doubt that, in spite of the honour bestowed on those who guide the plough and scatter seed, farming is in a very backward state. Chinese fruits are proverbially poor, tasteless, and often worm-eaten. Chinese vegetables are greatly inferior to those of Europe, while as regards horticulture the results are meagre in the extreme. The fact is that in the art of tilling the soil, as in most other arts, China is really backward. The Chinese have advanced to a certain point, and there stopped. It appears, to them, sufficient to pay an exaggerated deference to agriculture in the abstract, and, doing what their ancestors have done before them for centuries, to leave the results to Heaven."

COFFEE AND CHICORY.—The *Daily News* says:—"Some forty years ago coffee was coffee. Chicory was a *malum prohibitum*, a thing not to be tolerated. Then followed its toleration, not a full toleration, but a toleration coupled with a condition. The condition was observed in the use of the familiar packet announcing that the grocer sold the packet as a mixture. No other adulteration was allowed, and the result was most unexpected. The trade adopted the permission, but the public did not adopt the coffee, at least they did not do so for a long time. Chicory was legalized; but the increase in the sale of coffee did not keep pace with the increase in the census returns. And now the Revenue Act of the last Session starts coffee under new conditions. All sorts of vegetable substances may now be mixed up with the coffee of commerce, only the mixture must be sold as a mixture and in quarter-pound packets or packets containing an even number of quarter-pounds, with each quarter-pound subject to a penny tax. We may eat beans and turnips and dandelions—what the Germans call Gesundheits Kaffee—and there will be every variety of beverage and fluids with all names, at all prices, and with all properties. One variety, indeed, we probably shall not see. To the other mixtures which shall constitute the coffee of the future, chicory will not be added. The reason is not hygienic but commercial. Each adulteration bears its own special tax. Chicory brings in its own return to the revenue, and the beans and the dandelions would bring in theirs, and the British taxpayer won't pay both."

COFFEE IN BRAZIL.—Mr. Consul Ricketts, in his report on the trade of Rio de Janeiro in 1880, says:—"There is probably no country in the world more suited as regards soil and climate to the growth of the coffee tree than Brazil; but notwithstanding this, the production of coffee does not increase in the same ratio as it does in some other countries, such as the Philippine islands, central America, and Ceylon.* The same remark applies also to Java, where the coffee bean has for a long time past formed one of the principal articles of export. But this result has in each instance proceeded from different causes, for, while in the Dutch East Indian possessions it has been brought about more especially by the action of the Government, which—having taken upon itself the anomalous position of ruler and trader—placed numerous restrictions on the producer, in Brazil it has arisen from a system of labour, which, under any circumstances, could not receive much expansion; but what might not be effected as regards the cultivation of coffee if the present difficulties surrounding the question of labour were removed?"—*Produce Markets' Review.*

PEERMAAD HILLS TO PANDY LAND.—A fine road is the Peermaad road for 32 miles; it runs through a very pretty hilly country, which is well watered; nestled among the trees are comfortable looking houses, standing in their own gardens, with the never failing coconut, arecanut, sago palm and plantains everywhere. In the valleys are sugar cane and paddy, the latter largely predominating. Passing Varoor, 17 miles from Cottayam where there is a Traveller's bungalow, (with a cot, a table and two chairs by way of furniture) we pushed on to Kaogerapillay, 23 miles, where there are two houses belonging to planters; here we called a halt and spent the night, leaving again next morning, after early tea, and reaching Moondykyam (32nd mile) in time for breakfast. In sight of a bungalow on the top of a hill at the head of the Ghat, which certainly commanded a most lovely view, but the place wore an abandoned appearance, though there were signs of care and attention having been displayed in years gone by. We noticed some grevillia robustas, cypresses and a wealth of roses under the windows, with ivy clambering all over the walls; we noticed some tea, a fine kind of hybrid Assam, which appeared to be doing remarkably well, though apparently no attention had been paid to it for some time; and some peach trees, and the wreck of what had been a kitchen garden. Came in sight of the H—— bungalow and estates. Here we met with a hearty welcome,—the regular planter's hospitality, and we were soon made jolly and comfortable. After a glance at the Tote, which looked very flourishing, with heaps of coffee berries all over the trees, and a few on the ground, which the manager groaned over, as he said "Confounded winds, never saw such weather in my life as we've had; put a big crop on, and the wind comes and knocks off a dence of a lot"—but, planters, like farmers at home, are known to be fond of a grumble, and never like to own to being satisfied. For our own part, it struck us that you might sit under some of the trees, and pick coffee till you were blue in the face. We pushed on to the A — y, where the sporting owner showed us some of his magnificent trophies, bison, sambur, ibex and other heads; an exceedingly handsome liquor case, made out of an elephant's foot, attracted our attention. This estate, too, looked in wonderfully good heart. A visit to two or three more estates near by, all in a most promising condition, brought our Peermaad stay to a close.—*M. Mail Cor.*

* A very strange mistake, over-production in Brazil being the result of concentrating slave labor on coffee. —ED.

STOCK'S CARBOLIC ACID CURE for Coffee Leaf Disease, is, we regret to learn not turning out a success so far in Ceylon. On Warleigh estate, Dikoya, where it has been applied on an elaborate scale, the report is very qualified as to results, even though the coffee has the advantage of being interspersed with cinchona, so checking the spread of the spores. On Udapolla Liberian coffee again, Mr. Jardine has experimented with a mixture up to 25 per cent of the acid, without being satisfied that the fungus spores in the immediate neighbourhood were disposed of. In fact they were said to be ripening fast. Mr. Jardine will now try up to 50 per cent and watch the results as an experiment.

"SALT BUSH" AUSTRALIA AND INDIA.—Amongst the beneficial results of Mr. Buck's visit to Australia as Commissioner for India at the Melbourne International Exhibition, will probably be the introduction of the valuable salsolaceous plant, known in Australia as "salt bush." Originally regarded by the Australian settlers as useless or worse, it turned out to be one of the most nutritious cattle feeds in the world. Now it is likely to confer a double benefit on India. Not only is good cattle feed wanted, but a plant desiderated which will feed upon and rid the soil of the saline inflorescence called *reh*, the result of frequent irrigation and the cause of sterility. The Australian salt bush is being tried for these purposes in North Western India and with every probability of success. Query whether the salt bush might be successfully grown by the sides of marine streams and onthe sea shore and other places in the Northern Province of Ceylon.

THE CULTIVATION OF THE POTATO is thus discussed in the *Sydney Mail* :—"To obtain profitable root crops it is imperative to pulverize the ground thoroughly and to manure it highly. The first of those root crops demanding manure in large quantities is the potato, introduced into notice only some 260 years. It has found its way into every garden, and in the face of loud and constant assertions to the contrary, has proved itself a very valuabe and wholesome article of diet for man and beast. That mode of culture which shall at all times and in all situations tend to produce the heaviest crops and of the finest quality is of material importance, not to the farmer alone but to the consumer also. Mr. Knight, the late president of the Horticultural Society, in his admirable lecture on the culture of the potato, declares "that *light* is of the utmost importance to the growth of this plant, and advises all potato-drills to run north and south, thus insuring the greatest breadth of light daily. To plant old potatoes, good sized ones, none of less weight than four ounces, indeed he uses six-ounce ones in preference; each set to be six inches apart in the rows, and two feet six inches from the centre of one row to the centre of the next. One fact Mr. Knight mentions, and as it is of importance, I may quote it :—"The outer rows and single rows produce far more potatoes than those in the inside." The best soil, where you can choose it, for growing potatoes is light sandy and moderately rich land, if fine mealy potatoes are required. When potatoes are boiled or steamed carefully they are eaten by horses, cows, pigs, and poultry with the best results; but raw potatoes are not so fattening. In Tasmania as much as sixteen tons have been dug from an acre of land. Indeed, I have been told that carefully-selected seed will make the difference of two or three tons per acre. The potato prepares land for the wheat crop admirably to follow, having well manured the ground and ploughed it with a deep rather than a wide furrow, let it rest until you wish to put in your crop. Ash-leafed kidney or silver-skin may be planted in May and June; the end of July and August is time enough for the main crop. If you have a grubber put it through the land; then, with a light double mould-board plough, open it into ridges and furrows about two feet from centre to centre; but, if the land is rich, two feet six inches will be even taken; along these furrows lay evenly the manure, which should contain a large proportion of slacked lime and salt; on this lay the potatoes, and then, with a plough, split the ridges from end to end, covering up the tuckers and making fresh ridges with the manure, and potatoes as a centre core. We have no potato disease here, but a grub is sometimes troublesome. Lime and salt clears the ground of this pest speedily."

THE MOON AND THE WEATHER.—We observe that Sir W. Thomson, in his address on Friday week to the British Association, declared authoritatively that "careful observation with the barometer, thermometer, and anemometer, at the time of new moon, full moon, and half-moon, has failed to establish any relation whatever" between the phases of the moon and the weather. "If there is any dependence of the weather on the phases of the moon, it is only to a degree quite imperceptible to ordinary observation." It is difficult to account for the deep-rooted popular prejudice that the weather does change more, and with more significance, at the time of the phases of the moon, than at any other time. This is a point on which ordinary people will not accept scientific opinion. They raise their brows, and evidently think that vague, popular impressions must have more value than scientific observation. We wonder why. It seems precisely one of the matters which scientific observation should set at rest.—*Spectator.*

ALOE CULTIVATION.—On page 426 appears an extract from the *Indian Agriculturist* referring to aloe fibre. If aloe fibre is of such commercial value as is represented in the extract in question, a bright future is certainly in store for poor Jaffna. Perhaps, it is not generally known that aloe is a common plant in Jaffna. Uncared for, it grows luxuriantly not only in the peninsula, but also in other parts of the Northern Province. It is found in wild abundance in the Pachchellapally district. The species of aloe known in Jaffna are chiefly three, and their Tamil names are (1) *Kumarikaththadai* (?) *marel*) and (3) *Pullaikaththalai*. The first-named species attains a great height, and its stalks, measuring 6 or 8 feet in length, give it a noble appearance. It is common in Pachchellapally, and is a favorite fence plant with the coconut planters. A traveller by the central road may see it in unbroken succession, forming the boundary fences of the estates in the district. It is never watered nor any care bestowed upon it: yet there is hardly any other plant which grows so luxuriantly and rapidly as this. The late Mr. D. Todd who knew more of it than his fellow-planters, a short time previous to his death, cut down some which grew in his estate, prepared the stalks into fibre and took it with him to England. On his return he informed one of his friends in course of conversation that the aloe fibre which he took realized a good price, giving him a clear and an unexpected profit of R,000 on the whole transaction. This was the first and only transaction in Jaffna aloes, and Mr. Todd having soon after died, it is known to a few only. The other day the enterprizing broker of Messrs. Delmege Reid & Co. procured for his principals a small lot of fibre extracted from one of the species mentioned above. It was obtained from the Wanni, and, although it was not subjected to any patent process, yet it looked remarkably fine. It has been sent to England, labelled probably "Jaffna fibre." The result is anxiously looked for by all interested in Jaffna. The *marel* grows in Wadamarachy and may be seen in large groups in the plains of Semmani. The remaining species is a favorite medicinal plant with native doctors and is not so common as the others. Surely a cultivation which requires but little money and trouble must be at once undertaken, and there is no place in Ceylon so fitted for it as Jaffna.—*Cor.*

THE "FATAL FUNGUS" AND IND EFFECTS ON THE COFFEE TREE.

"W.'s" letter given below, will, like all his writings on coffee culture, be read with respectful attention. But in denouncing the popular belief in the fatal effects of the fungus, as unscientific, we suspect "W." himself will stand alone amongst scientific men. We are not aware that the quack who propounded the "internal ulcer" theory had a single believer in his absurd theory. We all know and believe that the evil is in the leaf. The fungus enters it by its stomata and feeds on the contents of the cells, the very life-blood of the plant, and crop after crop of leaves produced by the plant for its own sustenance, used for the sustenance of the parasite and then dropped, have a very different effect on the strength of the plant to leaves withering and dropping after they had performed their nourishing function. Under continuous attacks of the fungus and repeated attempts to renew foliage necessary to its own existence, which only go to feed its foe, the tree becomes so debilitated, that it cannot mature its fruit. Mr. Hughes has shewn, what no one knows better than "W.," that a tree can be exhausted by too frequent production of leaves, as well as by over-bearing of fruit crop. Wind is a terrible evil in depriving the coffee tree of its leaves and were tearing winds to become as permanent in existence and operation as *hemileia* the effect on the coffee bushes would be much the same. But bad as "wind, wash and weeds," the planters' three great enemies are, the three combined, do less mischief than the ever present and almost ever active fungus.

With all respect to "W.," we feel it right to say that we adhere to our opinion. It is that while coffee has suffered much from abnormal seasons in the past decade of years, and from other causes,—notably insect pests,—its great enemy has been, and continues to be *hemileia vastatrix*. Even when torn off by winds, leaves gave back fertilizing mineral matter to the soil. In the case of leaves destroyed by the fungus, the fertilizing matter has gone to feed the parasite and increase its power for mischief. Other causes, many and potent have worked against the coffee tree and those dependent on it. But the sudden development of a new fungus, peculiar to coffee in 1869, its rapid spread and its "fatal" effects, have done more harm to the coffee enterprize than all other causes combined. If the virulence of this one pest abated, we should soon cease to ask the question "What ails our coffee?"

WHAT AILS OUR COFFEE TREES? No. 6.

SIR,—*Hemileia* has evidently become far too convenient a scapegoat, and has been too long accepted to be easily relinquished by many who have accustomed themselves to imagine it an adequate cause of the recent infertility of our coffee trees, notwithstanding that the theory is equally opposed to logic and to facts.

The only correspondents who defend the fatal fungus theory with any show of reason assume that the pest was carrying on its destructive work insidiously and universally on our estates prior to 1871, although it was unobserved except on a very few. Before the true nature of the *Hemileia* and its attack was fully ascertained, some high authorities believed the pest to exist unseen in the internal tissues of the trees, and to develop itself there unobserved. But this hypothesis was always doubtful, and was eventually demolished by Mr. Ward's complete exposition of the life history of the fungus, and the precise method of its attacks. The *external* origin of the disease was thus fully established, and it was proved conclusively that the leaf was the sole seat of the attack, and that the operation of the disease is therefore manifest. The assumption that *Hemileia* might have been insidiously carrying on unseen mischief is therefore entirely erroneous, and the only argument by which the universal failure of crop in 1871 could be attributed to leaf-disease falls to the ground. In fact, as has already been shown in previous letters, the theory of the fungus being the potential cause of the short crops of the past decade is logically untenable, inasmuch as the alleged effect preceded the cause. And it is also opposed to fact, as there has been throughout the decade the greatest discrepancy both in point of time and intensity between the so-called cause and its operation.

Setting aside, however, both the logical impossibility of the theory and the utter want of sympathy between cause and effect, as thereby implied, it may be instructive to consider the subject from another point of view. Seeing the almost universal prevalence of fungal attacks on vegetation, and that coffee is by no means exceptional in having its fungal parasite, it is well worth considering whether, and to what extent, *Hemileia* and its effects on our coffee leaves differ from other parasitic fungi and their ravages on the vegetation around us. If we stroll through the jungle, or along any path in the country, innumerable forms of fungi will meet our view, both on the fallen leaves which are shewn on the ground, and on many leaves still living and clinging to the trees and plants. Few plants, indeed, will be found to be exempt from the ravages of fungi in some form or other. Parasitic fungi are no strange phenomena, but are almost as universal as vegetation itself. Yet we hear no jeremiads on the havoc so committed all around us. No doom is pronounced against the jack, and many other of our most useful trees, which, nevertheless, suffer as much as our coffee trees, or more, from precisely similar kinds of attack! A few weeks ago, on pointing out to a fellow-planter who was with me a fearful dose of fungus on the leaves of one of our new and most hopeful products, and asking him how it happened that no *scare* had been got up about this invader, he merely remarked that it seemed "*so natural*" he had not regarded it as a *pest*! In fact, it was *quite natural* and the leaves in question were only going the way of most leaves. The alarm about our *Hemileia* was inspired by the belief that, like the potatoe perenospora, it existed in the internal tissues of the tree, and infected its whole economy. All serious fears ought, therefore, to have subsided when the true nature of the fungus and the method of its attack were fully ascertained. Before this discovery, however, it had been generally accepted as the cause of all our misfortunes, and was not so easily dismissed from the pre-eminence it had attained. Many will still cling to the fatal fungus theory, and probably regard me as a personal enemy for trying to deprive them of it.

The history of a leaf is like that of all vital organisms in having a period of growth, or cycle of life-changes, during which it fulfils its appointed functions for the plant to which it belongs, until it attains its full maturity, when these life changes and these functions cease. The leaf is then no longer an active member of the society in which those life changes and functions were fulfilled, but passes through death into a passive state, and becomes subject to a new cycle of changes, in the course of which its substance is either recomposed or dissipated. The passive remains of the once active organism may still cling to the place of its birth and activity, but its work is done! It is but a corpse, and the undertaker, if he have not already with indecent haste anticipated the event, is ever ready to begin his work. The defunct

leaf is thenceforward subject to a new cycle of change, wholly irrespective and independent of its former life and connexion. Whatever may thereafter happen to the leaf, whether it shrivel and dissipate under the slow process of eremacausis, or become food for insects, or be assimilated into fungi, matters not to the plant it once served as lung and stomach. A dissolution of partnership took place the moment the leaf ceased its growth and active functions, and no further vital connexion subsists between them. The useless leaf goes like the old horse to the knackers! What matters it to the brave old oak that 200 undertakers are ever attent to dispose of his used up limbs? or to the pine that 100 fungi will wake over the fallen or falling members of his communion? or to the lime that some 70 claimants will scramble for his old clothes? Then, why should King Coffee give up the ghost at the sight of *two* poor body-snatchers? By the bye, why has one of these been raised to the highest pinnacle of fame, whilst the other has been relegated to share the fate of the handbook? Why has poor sphœrid been denied the honour or shame of its share in the fatal transaction, and dropped as completely as though it had never been heard of? It derives its nourishment, however much or little that may be, from our coffee leaves, and seems by Mr. Morris's account to be always present. At any rate he always found it when required.

Mr. Ward has proved that whatever mischief *Hemileia* is in its nature capable of doing is done to the *leaves*, and even to them only whilst they are growing, and fulfilling their proper functions. It matters not to the coffee trees what becomes of its leaves after they had passed the growing stage. That is certain. Surely it cannot then be a very difficult matter to estimate the extent of possible harm our enemy can do us, when we know so exactly how to measure its operation! The leaves themselves are our witnesses, and will furnish full and conclusive evidence. How then do they appear? Are they puny, stunted, half-grown cripples, testifying to a desperate, life-long struggle against some superior foe? Look at our coffee trees! Were they ever more handsomely clothed than they now are? Or was their foliage ever brighter in colour, larger in size, or more luxuriant? Even the corpses of the leaves, as they lie scattered on the ground, are not like victims of weakness and starvation, but resemble well-nourished veterans who have borne the heat and burden of the day, having attained a full maturity of growth, and therefore having done their duty and fulfilled their appointed functions. Contrast the victims of *Hemileia* with those of *wind* or insects: cockled, stunted, discoloured, and misshapen. Consider the quantity of foliage thus annually lost during the prevalence of severe winds, and bear in mind that the foliage so destroyed is cut off or injured in its youth, when its active functions are not merely interrupted, or abridged, but destroyed. Yet our trees have always been subject to this serious loss of leaf by wind, according as they were more or less exposed, and, though they have no doubt suffered thereby to some extent, it has never inflicted any such fatal infertility as is now attributed to the loss of leaf by *Hemileia*.

The fact that the vast majority of all infected leaves attain their full size proves beyond question that any abridgment of their life, or lessening of their functional work they may suffer by leaf-disease must necessarily be brief and limited, and quite incapable of producing such ruinous consequences as we now deplore.

Fall of leaf is of course an important factor in weighing the effects of *Hemileia*, and it is one regarding which much misconception exists. Some planters regard almost all fall of leaf as attributable to the fungus, and overlook the fact that all leaves have a natural period of growth, and an inevitable time of fall. Coffee trees have two periods of fall in the course of the year; and are liable, besides, to loss of leaf from weeds, wind, or crop. In days of old, when weeds predominated, loss of leaf often occurred to an extent which even the worst attack of *Hemileia* could not surpass. The familiar sign of leaf distress, the fading colour of the foliage, first yellow, and then, if prolonged, a sickly white, betokened a heavy dose of weeds, or else a bumper crop, or both combined; and was always followed, if relief were not speedily administered, by a tremendous fall of leaf, leaving the trees as bare and sticky as the worst attack of modern leaf-disease! Yet, although the loss of leaf in such cases involved a total interruption of active leaf-work, there was no such resulting infertility as is now attributed to the loss of leaf inflicted by the fungus. The combined strain of a heavy crop on trees so divested of their growing leaves, and robbed at the same time of their proper nourishment by weeds, never produced *infertility*. The trees so tried no doubt suffered at the time, but they speedily recovered and yielded fresh and abundant crop. Many of these very trees are now, in their old age, equal in vigour to their youngest neighbours!

In whatever light regarded, and by whatever test tried, the fungus theory of the present infertility of our coffee trees is utterly untenable. This conviction forced itself on my mind long ago, and has been confirmed and strengthened by all subsequent observation and experience. For some time I abstained from any public discussion of the subject, as it did not appear to tend to any important advantage. Latterly, however, it seemed worthy of notice as a barrier to the discovery of the real ailment of our trees, and also as possibly saving us from scares in regard to other and newer enterprizes which are, or may be, affected by similar fungal attacks. Scares are unmitigated evils, and the liability to them is a perpetual source of danger and anxiety. The fatal fungus scare has lived too long, and should be reduced to its proper value by thoughtful research and the light of science.

The destruction of leaf tissue by insects, and some other cognate matters, which should have found a place in this letter, are necessarily precluded for the present at least by the unreasonable length it has already attained. I must conclude by reminding my fellow-planters of the great difference there is between the power of producing leaf and that of bearing fruit. Whatever the mystery of *fertility* may be, the fact that it is not co-equal with vigour of growth or production of leaf is one of every day's experience. We see plants and trees of most luxuriant growth refusing to flower, and others flowering profusely without a sign of fruit. Even amongst our coffee plantations are fields of most vigorous growth, which we have never been able to coax into crop bearing, and such fields existed and exercised our patience and ingenuity long before we had the scape-goat *Hemileia*, on which to lay the blame.

We want more light, but those need not expect it who keep their shutters up. W.

CUPREA BARKS RECENTLY IMPORTED FROM THE EASTERN PART OF THE UNITED STATES OF COLUMBIA.*

BY M. ARNAUD.

Until recently, only the northern "cuprea" barks, coming from Buccamaranga, in the province of Santander, were known. Having received several specimens of these barks from another part of Columbia, I propose to give some details of the examination I have made, both of the "cupreas"

* Paper read before the Union Scientifique des Pharmaciens de France (*Journ. Pharm. et de Chimie*, [6], v., 560.

from the north, and of two new types of "cuprea" from newly explored regions. The "cupreas" of Buccamaranga have now been imported into Europe for several years, and more recently in such quantities as to cause a considerable fall in the price of sulphate of quinine. This fall was due not only to the large consignments that were received, but also to the expectation of others, it being announced that vast forests of the trees yielding these valuable barks existed. This is now known to be incorrect, and unfortunately it is possible that the Buccamaranga "cuprea" will become rather scarce.

The "cuprea" barks have quite a special, very compact appearance. They are remarkable for their great density, which exceeds that of all other quinine barks; the apparent density varying according to my experiments from 1·128 to 1·180, taking water as unity. They are therefore easily distinguishable from all cinchona barks, except "pitayo" and "calisaya;" like these latter, the "cuprea," instead of floating on the surface of water, sinks immediately to the bottom.

The transverse fracture of "cuprea," after it has been trimmed with a knife, is characterized by a horny appearance. All the cells are, in fact, filled with a gum-resinous matter that is not present in the ordinary cinchona barks. Notwithstanding this appearance, which is so different from that of good cinchona barks, the "cuprea" bark contains sometimes upwards of 2½ per cent of quinine. It is therefore a valuable bark and justly sought after. The following shows the percentage obtained in analyses made of several samples coming from Buccamaranga:—

	I.	II.	III.	IV.	V.	VI.
Quinine	1·60	1·68	1·80	1·38	1·29	0·99
Quinidine... ...	0·47	0·57	0·57	0·37	0·55	0·36
Cinchonine ...	0·54	0·55	0·54	0·45	0·60	0·55

This bark has been described by Professor Flückiger* from a botanical point of view, and M. Planchon has recently published† an interesting paper on the microscopic sections of "cuprea." On the other hand, Mr. D. Howard‡ has stated that cinchonidine is entirely absent from this bark a fact that is confirmed by all my own analyses. The absence of cinchonidine constitutes therefore a perfectly distinct character of this species, in addition to its great density.

In order to give a correct idea of the densities of these barks I will give here some results that I have obtained with specimens for which I am indebted to the kindness of Professor Planchon, and with typical barks determined by M Weddel. As far as possible, I selected barks of the same thickness, taken from the trunk or large branches, so as to have them not differing much in age.

Genus Cinchona.

Water=1.

Cinchona lancifolia	0·617
Cinchona rosulenta	0·614
Cinchona cordifolia (Weddel's coll.)... ...	0·844
Cinchona succirubra	0·915
Cinchona Calisaya (from Planchon)... ...	1·021
Cinchona Calisaya (Weddel's coll.)... ...	1·064
Cinchona Pitayensis (from Planchon) ...	1·077
Genus Remijia ("Cuprea.")	
Cuprea buccamaranga	1·128
Cuprea llanos, north	1·179
Cuprea llanos, south	1·160
Bark yielding cinchonamine	1·320
Genus Cascarilla.	
Cascarilla magnifolia (Weddel' coll.) ...	0·958

The considerable variation in the apparent densities will not escape notice; first amongst the cinchona barks themselves and then between them and the "cupreas," for it is now certain that the "cuprea" barks do not belong to the genus *Cinchona*, but to a neighbouring genus.

I will turn now to the new "cupreas" which are the special subject of this note. I have received two series of specimens from the Cordillera regions, opposite the *llanos*, or immense plains which in the eastern part of the United States of Columbia extend down to the Orinoco. The first series of these specimens came from the *northern* part of these mountains; the second came from the *south*.

The "cuprea" from the northern part much resembles in appearance that from Buccamaranga, it being very hard, durable and dense. It is of a dark red-brown colour, and has a mean density of 1·179. The following are the percentage results of analyses of three specimens, being those presenting the greatest difference in alkaloidal contents amongst all the barks from this district that I have analysed:—

	I.	II.	III.
Quinine...	0·39	0·57	0·78
Quinidine	0·36	0·45	0·72
Cinchonine	0·72	0·66	0·67

The richness in alkaloids, and especially in quinine, is much less than in the "cupreas" from Buccamaranga, at least in the ten or twelve specimens that I have analysed.

The second series of "cupreas," from the southern part of these mountains, appears, as far as can be seen, to be more important. This bark is of a lighter colour than the two types above-mentioned; it is also very compact and dense, its mean density being 1·160. In alkaloidal strength it is very variable, but I have one specimen nearly as rich as those from Buccamaringa. The following are my determinations:—

	I.	II.	III.
Quinine...	1·35	0·51	0·48
Quinidine	0·48	0·49	0·48
Cinchonine	0·99	0·81	0·80

It may be remarked that these three types, coming from different districts of Columbia, possess physical properties and a chemical composition which allow of their immediate recognition as "cupreas," apart from their external appearance. Indeed they all contain a large proportion of quinidine. Sometimes these barks even contain as much quinidine as quinine, whilst in cinchona barks quinidine is relatively rare, at least in appreciable quantities. On the other hand, in the "cupreas" there is a total absence of cinchonidine, the alkaloid that occurs so widely and so abundantly in some Columbian barks. The great density of these barks as compared with ordinary cinchona barks has already been referred to.

For all these facts there is a complete explanation, since M. Triana, the eminent Columbian botanist, has shown that the "cupreas" do not belong to the genus *Cinchona*, but to the very closely allied genus *Remijia*.*

The occurrence of barks relatively rich in quinine that are not derived from cinchonas is a very important fact, and it seems to me the more interesting because the "cupreas" appear to be met with throughout the Columbian Cordilleras, and possibly in all parts of the Andes where the cinchonas are usually found. This expectation appears to be warranted by the two series of "cupreas" received by me from the *llanos*. The "cupreas" differ so completely from the cinchonas that it is easy to understand how they have hitherto escaped the search of the American exporters, and it will yet be some time before it can be ascertained what may be expected from the riches of the American forests in "cupreas."

It is now only remains to establish the identity of quinine extracted from "cuprea" with the quinine from cinchona, and the following experiments are perfectly conclusive on this point. The sulphate of quinine obtained from "cuprea" bark crystallizes very well. It presents the appearance of ordinary sulphate of quinine and gives the same reactions. Further the rotatory power of the sulphate in acid solution leaves no doubt as to the identity. The following results were obtained with a solution of the sulphate in 10 c.c. of normal hydrochloric acid diluted with water to 25 c.c. π=0·490 gr.; λ=0·220 m.; v=25 c.c.; a_D =—9·70; the temperature being 12° C., which gives $(a)_D$ =—224·8.

Pure sulphate of quinine from cinchoua bark, under the same conditions, show an average rotatory power that is practically the same, or $(a)_D$ =—225.

In conclusion I would remark that as it is now evident that quinine occurs in other than cinchona barks, it will be desirable to search for this alkaloid in the barks of the genera allied to the cinchonas, which, perhaps, like the "cupreas," might contain it in considerable quantity. —*Pharmaceutical Journal.*

* *Neues Jahrbuch f. Pharmacie*, xxxvi., 296.
† *Journ. de Pharmacie et de Chimie*, [5], v.
‡ *Pharmaceutical Journal*, [3], xii., 528.

* M. Triana determined the botanical genus and species of the "cupreas" with leaves and fruits coming from the same trees as the barks analysed by me.

TREATMENT OF FIBRES.

The following communication appears in the *Journal of the Society of Arts*:—

Having observed the remarks made by Mr. Thomas Christy respecting Mr. Ekman's "process for the treatment of different fibres," printed in your *Journal*, No. 1,543, Vol. xxx, dated the 16th June, 1882, I take the liberty to call to your attention my patents, No. 4,419, and No. 5,532, for the "production of solvents and manufacture of pulp," and believe that any kind of fibre can be properly dissolved by my process in a cheap and practical way. I use my inventieu principally for wood and straw, at my mills at this (address about three miles from Gothenburg), but I find also its practicability and excellent effects on jute and esparto, and would have no objection to make experiments with any other kind of fibre, such as rhea, if some one interested in this process would communicate with me, and furnish the necessary quantity of material.

Korndal Molndal, Sweden. D. O. FRANCKE.

PEACHES.

The great fault in peach culture is too thick training—crowding of the shoots during the growing season, which weakens them and hinders their early and complete maturity. The other day I measured a shoot of a remarkably vigorous and fertile Victoria nectarine here, and found the width, from the points of the leaves on each side, to be close upeu 16in. As it is the common practice to tie in the shoots from 3in. to 4in. or 5in. asunder, it will be seen how much the foliage must be crowded. He would be considered an incapable who trained vines so thickly. We have yet to learn what the effects of training peach shoots sufficiently far apart to expose every leaf fully to the light would be. That it would result in the production of annual shoots of a far more robust description than we are accustomed to see, and fruit of proportionate size and quality, no one can have any douht, and, if we are to improve in our culture, this is the direction in which we must go.

Those who grow peaches for profit must divest themselves of the notion that mere training is the chief end and aim of culture. In the nervous fear that trees will become bare of branches at their base, some cultivators are prevailed upon to shorten the tops unnecessarily when the tree has the best chance of bearing and growing, and many a peach wall has been half destroyed from this cause. So long as one can get fertile wood in plenty all over the tree (and under the most unlimited extension this is quite easy, as we can testify by trees nearly twenty years of age now), it does not matter in the least how or where the wood is originated; but that well furnished trees can be secured by this mode of training, and preserved in excellent health and fertility, we are prepared to prove by the trees themselves, in spite of all the prognostications of critics.—*Field*.

WIRE FENCES, AND BRACING THEM.

A good fence on the farm is of the greatest importance, and suggestions as to the best kinds, and the building of them, are valuable. There are but few sections of our country where any fence can be erected so cheaply as the common barbed wire fence, now being used so extensively throughout the Western States. A wire fence, properly put up, is as effectual in turning stock, which has become accustomed to it, as a stone wall or a board fence; and although an animal may be occasionally injured, there is on the whole but little danger to be apprehended in using it.

Four wires, all barbed, are generally used. The fence could be made much cheaper, and nearly or quite as effective, by using two strands of common wire in connection with two barbed wires, placing them alternately, a barbed wire at the bottom, about one foot from the ground for cattle, and closer for sheep. To turn horses and cattle, it is well to fasten a strip of lath, whitewashed or painted white, to the top wire. This aids the stock in determining the proximity to a fence in the dusk, when, without this, they might run into it and be injured.

The most essential thing to observe in building a wire fence is the bracing of the end-posts. They are usually braced from the inside, which I think is a mistake, as the wires always have a tendency to lift the posts from the ground, and thereby become slack. A far better way is as follows: Take a 3-inch rod and bolt one end through the post, between the uppermost two wires, and fasten the other end of the rod to a large stone or log, sunk three or four feet below the surface on the outside of the post. When it is desirable to drive nearer the end post than the brace will allow, the second post may be braced, and the support carried to the end-post by means of a piece of scantling. Braced in this manner, the wires have a tendency to pull down the end-posts instead of lifting them; and when the work is properly done, a fence will remain in place, and be of service until two-thirds of the posts have rotted off. A stretcher is not only convenient but necessary in facilitating the construction of a well-built wire fence.—F. H. MCFARLAND, Dallas Co., Iowa.—*American Agriculturist*.

BRAZIL TAPIOCA.

A discussion has been going on in Ceylon as to the feasibility of employing European capital and enterprise in the cultivation of manioc or cassava, either for human food or the manufacture of glucose, and the same subject has also cropped up in Jamaica. There seems little doubt that in suitable soil and under proper management this industry would prove most profitable, but there is a kindred cultivation which might as easily be introduced, the prospects of which are even more promising, we mean that of Brazil tapioca. Now Rio tapioca is as much superior to the common flake tapieca as rice grown in Carolina is to rice grown in Moulmein or Arracan. Rio tapioca is also as much superior to the East India tapioca, as Bermuda arrowroot is to potato starch. The tapioca should be steeped in water twelve hours before it is cooked. It is highly recommended as an excellent food for either the healthy or sick, for the reason that it is so quickly digested without fatigue to the stomach. So greatly is Rio tapioca esteemed in Europe for the superior properties it possesses, combined with the high price paid for it, that the quantity shipped to the United States except by special importation, is very small. Five years ago an enterprising firm in New York city, knowing its worth, imported a shipment, but so little was its value known in that country, that it had to be sold to be made into Brazilian arrowroot. Brazil tapioca is generally packed in barrels, while East India is put into bags of about 100 pounds each. The natives in India frequently eat the simple root, after having roasted it in hot ashes, without any subsequent preparation. The leaves are also boiled and eaten by the natives, who frequently ferment the juice with molasses, and make an intoxicating drink called noyeau. So great is the productiveness of the manioc or cassava plant, that it has been calculated that one acre of it will yield food for more people than will seven acres of wheat. Necessity is the mother of invention; such has been the havoc made by the Colorado beetle on the potato crop in America that it no longer pays to grow potatoes to make potato starch. An enterprising New Englander has with great success planted the manioc or cassava plant in Florida, and has raised a crop so large that a company is about being formed to manufacture it into starch.—*Planters' Gazette*.

THE QUILLAI TREE IN CHILI.

While steps are taken to replace the quillai trees which are destroyed annually, the probable extinction of this valuable plant in Chili is attracting the attention of foreign countries, as may be seen from the subjoined article from the San Francisco "Bulletin." The quillai is not likely to disappear from Chilian forests quite so soon as the "Bulletin" appears to anticipate; nevertheless, now that the bark of the tree has become an important article of exportation and is much sought for in Europe, the inroads on the valuable plant will naturally increase yearly. Under these circumstances some steps ought to be taken in time to preserve an indigenous tree of so great value from utter destruction at no very remote period, otherwise a succeeding generation may be witness of the strange anomaly of Chili being tributary to other countries

for a supply of what is pre-eminently a Chilian product. The article referred to is as follows:—"Possibilities of horticulture in California are so great that hardly a tithe of what might be grown here is in any way tested, nor can be for many years to come. But there is a South American tree of commercial and peculiar value which deserves immediate attention. Baron Von Muller, of Melbourne, Australia, a veteran botanist, and a man of large and practical attainments, who has established forests and botanic gardens in many places, calls the attention of the Australian public to the Quillaja Saponaria (the soap tree of Chili). An English journal asserts that the tree is fast disappearing from the forests of Chili, its chief habitat, owing to the recklessness with which the natives strip off the bark, which contains the saponaceous element. It also says that for dressing silk and wool, chemical science has not yet discovered any equally efficient substitute for this bark, and it has accordingly come into large demand both in France and England. But Australia and New Zealand, being great wool-producing countries, are interested in procuring a supply of such a powerful alkaloid. There is, therefore, a decided anxiety in these countries to plant quillaja groves. But California has equal if not superior advantages for its culture. Seeds of quillaja have twice been distributed on the Pacific Coast by the "Bulletin," and quite a number of small trees from these importations are thriving in various parts of California. The alkaloid from the bark of this tree is also coming into use as a cooling and healthy wash for the hair, and as a component part of various preparations used by barbers and hair-dressers. There is likely to be a scarcity of quillaja bark in a few years, and plantations of the tree might with profit be established on the hills of this State."—*South American Journal.*

ABOUT CORK AND ITS USES.

Thirty years ago, it is said by old dealers, there was not one-tenth as much cork used in the United States as there is today, and the rate of increase is not only steady but rapid. A reporter who has been investigating the matter for the *Times*, gives some information on the subject, which is undoubtedly true, but not very new. A chemist in this city, he says, when applied to for information, frankly admitted that he had always had an idea that cork had no chemical properties. He looked over his authorities, however, and ascertained in an old chemistry that when treated with nitric acid, cork was found to contain proportions of white fibrous matter, resin, oxalic acid and suberic acid. The latter is an acid not in practical use and is comparatively unknown among the dealers in chemicals. Cork has a very high percentage of carbon, and when treated in the same way that wood is burnt to make charcoal, it produces a pigment known as Spanish black, which is used to a slight extent among artists to procure certain dark tints. It is claimed by some American dealers that cork can be profitably grown in the Southern States, and a few modest efforts have been made in that direction in Georgia and Florida. A New York cork importer said that he had seen American-grown cork, and thought it of a very good quality, but he had never seen any of it in the New York market, and had heard of no attempts being made to introduce it here. England and Russia used by far the larger quantity of cork, the people of those countries applying it in a hundred different ways, both domestically and scientifically.

There has been a great deal of the rough bark of the cork tree imported lately. It is called virgin cork, and looks very much like the bark of an oak tree. It is quite cheap, and is used for decorative purposes in gardens and conservatories. Florists also use it to some extent in their fancy designs. Rustic devices made from virgin cork may be seen in several of the handsome grounds along the Hudson River and on Long Island. In England* it is extensively used in the public parks and in the formation of picturesque grottos in private estates. A gentleman who visited Portugal and Spain as buyer for a New York cork firm last year, says that in that country the cork bark is used by the peasantry for cradles and chairs, beds and sofas, and even to make houses of. He saw scores of little row-boats on the small rivers of Portugal which the cork cutters had hastily fashioned out of virgin cork. Some of these boats were large enough and strong enough to hold six or seven persons. So cheap is the virgin cork, even in this country, that enough can be purchased to tastefully ornament a whole garden for $10 or $15.—*Drug News.*

* And in Australia.—ED.

THE BEGONIA,

(which must not be confounded with *Bignonia*) is a plant conspicuous often on watery rock faces in Ceylon, having pretty pink blossoms. That that this is only one of many varieties, enormously multiplied by the gardener's art, is evident from an article in the *Asian*, from which we quote:—

There is probably hardly any other genus of plants that has been either so much improved or have attained such a degree of popularity in such a short period as has the Begonia during the past few years in Europe, and also to a some what less extent in this country. This is scarcely to be wondered at when we consider the ease and rapidity with which they can be propagated, either from seed or cuttings, and many of them from leaves or parts of leaves only; and certainly as foliage plants a large section of them occupy a unique position in plant society; for what other genus of dwarf ornamental plants have we that can be compared with the beautiful foliage of the immense number of new varieties of what is known as the "Rex Section." Of this large family, with their bold fantastically marked leaves, embracing almost every shade of colour, from pure silvery white, through all the shades of green to the deepest black and frequently also blended with pink, crimson, and maroon, the original parent of this large group "*B. Rex*," a native of this country, has been so far outdistanced by the beauty of its numerous progeny that it has been almost entirely driven out of the field, and yet scarcely ten years since it was the only variety known in our gardens. It is not, however, as a foliage plant that the Begonia has made such rapid strides to attain popularity in such a short period, but as a flowering plant; and in Europe at least it bids fair to rival even such old-established favorites as the Geranium or Calceolaria as bedding plants, being equally hardy and more diverse in its various shades of colouring. These now form an entirely distinct class, and are known as the "tuberous-rooted section," the history of which is certainly interesting. The parents of this group are *B. boliviensis*, *B. Veitchi* *B. roseflora*, and *B. Pearcei*. The first hybrid variety raised was *B. Sedeni* by that prince of hybridisers Mr. Seden in 1868, and since that time the number of named kinds sent out might be reckoned by the thousand, and it is computed that at the present time there are at least six hundred standard varieties in cultivation. During this brief period of fourteen years an immense improvement has been made in the size and form of the flowers, which in some of the best of the new varieties it is stated measures nearly six inches in diameter; but undoubtedly the crowning triumph of all was the introduction of varieties with perfectly double flowers in 1876. There has since then been a great addition to the list of these also, and vast improvement made in them, some of the new varieties being described as being as perfect in form as a Camellia.

THE DECLINE OF COFFEE IN CEYLON.

SIR,—In reading through "W.'s" letters on the decline of coffee in Ceylon, and the various agencies which may, or rather, according to him, may not have brought about the present lamentable results, I fail to notice any allusion to a most important point, viz., the nurseries, the source from which every estate must trace its origin.

Now to digress a little. There are but few cultivators of cinchona, who have not had to mourn the loss or debility of their plants in all their stages, from the unsuccessful nursery to the fast diminishing three year old plantation. This is chiefly attributable, no one will attempt to gainsay, to the folly displayed in the purchase of most of the seed, and the carelessness with which it was collected. I am certain that more than half the seed sold was quite unfit for propagating its kind, either on account of the immaturity of its parent, or its own unripeness. I could dilate much

further on this point, but it is coffee not cinchona that is my text, and my allusion to the latter is but to use it as a parallel case to strengthen my argument concerning the former.

We planters of the present generation flatter ourselves, if we had had the opening up of the old coffee districts of Ceylon, that with our enlightened views, for many succeeding decades they would continue in their pristine vigour, and be veritable mines of wealth, even at their present advanced age. Now what grounds have we for making any such proud boast, where with all our vaunted knowledge so many have failed to pay cinchona, within the last few years, the necessary attention due to the first proceeding on planting any product, the healthy source of the plants to be cultivated. If, with all our experience, we have acted so foolishly of late, what grounds have we for supposing our forefathers exhibited more discrimination? Were our coffee nurseries of yore planted with carefully selected seed, fully ripe, off well-grown fully matured trees? Then, having begun so far well, was a careful selection made of the plants raised when about to be transferred to their permanent abode? I trow not, judging from the care I have seen displayed generally, during even the last few years, in the planting up of clearings. I have seen coffee and cinchona nurseries planted out with no selection of plants, and the refuse of other nurseries eagerly accepted by needy neighbours. I have known seed collected from two year old succirubras for sale, and large packages of unripe seed eagerly bought. We have surely no one to thank but ourselves for the accumulation of evils emptying their vials upon our heads. This same haste to be rich is displayed in every branch of our planting, and we shall soon have to weep over fruitless plantations of other products, if seed from three year old cocoa and eighteen months rubber continues to be germinated. On coffee this pratice may not have exactly the same result as on other plants, but we may surely trace future barrenness and early decay of primaries in great part to some such cause.

"W." wishes us to believe that to have bred inherent weakness in our coffee trees would have required many descents. I think not; a flaw one generation back is sufficient to effectually debilitate the immediate offspring. The propinquity of a bad tree unfit for reproduction will contaminate the pollen of a well-nurtured one in juxtaposition, and cause the failure of any plants raised from their stock.

"W." also remarks that he has seen an opened flower form fruit, which cannot have known any extraneous helps to fertilization. Now is any fruit so formed, naturally healthy, and fit for sowing? Would it not rather be degenerate from weakness brought about by too great a strain on the unassisted powers of a spinster flower?—"V."—*Ceylon Times.*

PRUNING AND TRAINING THE TOMATO.

A correspondent asks us to give precise directions for pruning the Tomato, with illustrations, in the same manner that we have done for the grape-vine. It is not practicable to do more than to give general directions, to be applied as the condition of the plant may require, as in an herb like the Tomato, we do not find that regularity of growth presented by the vine. The Tomato plant continues to grow, and to form new stems and new flower buds as long as warm weather lasts, and when the growth is stopped by the first frost, it will be loaded with a large quantity of green fruit of all sizes, as well as many flower buds. Here is a great waste of strength in the plant; it sets and contributes to the partial growth of a large quantity of fruit that can never mature. One of the first steps in the garden culture of the Tomato should be, to prevent the partial growth of all the fruit that can not be ripened. Of course no definite rule can be given as to the quantity to be removed, but each one must exercise his judgment. It is assumed that the plant is trained to a support or trellis of some sort, otherwise pruning would be of little use. One object in pruning should be to remove the superfluous small branches that are produced in abundance, and make a dense, confused mass of foliage. The pruning to remove the excess of fruit may be combined with this; the later flowers are borne upon the small, recently grown branches, and by removing these altogether, two ends are accomplished. When one of the main branches of the plant has set all the fruit it can ripen, it should be stopped, or prevented from growing any longer. An inspection of the Tomato plant will show that it produces its flowers and fruit in a different matter from most others. A flower-cluster generally springs from an axil, or where the leaf joins the stem, or, as in the grape, appears at a point opposite to the leaf, while it is in the Tomato midway between two leaves, as shown in the diagram. In stopping the growth of a stem, there should always be a leaf left above the cluster, the line in the diagram showing where to cut; if desired, as a precaution against accidents, two leaves may be left; in this case removing the upper flower-cluster, should there be one above that which has been fixed upon to be the last one upon the stem. When the fruit is partly grown, it will be well to remove all that are deformed and misshapen, and if a cluster promises to be unusually heavy, it will be well to support it to the trellis by a bit of string. Thinning the crowded branches, removing the excess of fruit, and stopping the growth of stems after they have set sufficient fruit, are the ends to be aimed at in pruning the Tomato, and in these one operation usually includes the others. In applying these general rules, which are all that can be given, one, in the first attempt, is not in danger of pruning to excess, but of leaving too much. Those who grow the vegetable in field culture, gathering the fruit by the bushel, and wasting as much as they use, may ridicule the notion of training and pruning the Tomato. Many who have small gardens, and wish to make the most of them, find it a great saving of space, besides giving the garden an air of neatness to train the Tomatoes to a trellis, and if this is done, pruning becomes a necessity. The ease with which the Tomato can be grown in our climate has led to its neglect, and we rarely have the fruit in its best condition. Some, who are fond of Tomatoes in the raw state, pay as much attention to the quality of the fruit as they do to that of an apple or a pear. Such will find that Tomatoes cultivated with care, fully developed, and thoroughly ripened in the manner indicated are so greatly superior to those grown in the usual hap-hazard way, as to warrant the slight trouble it involves.—*American Agriculturist.*

NOTES ON USEFUL MYRTLES.

BY JOHN M. MAISCH.

One of the myrtles of tropical America has been introduced into and naturalized in most other tropical countries, where it is highly valued on account of its fruit, which resembles a medium-sized pear with a downy, veined, brittle and thin rind, and containing a whitish, yellowish or reddish pulp, of a very agreeable sweet, acidulous and aromatic flavour. The fruit is known as *bay plum*, *guava* or *guayava*, and in Brazil as *araca mirim* and *araca goiaba*. It comes from a small tree, the *Psidium Guava*, Raddi, under which name two or three nominal species are comprised, chiefly distinguished by the shape of the fruit; this is either pyriform or globular, the latter apple-shaped or red guava being regarded as rather inferior to the former, or white guava. The unripe fruit is astringent, and is employed like other astringents; the young leaves and buds have similar properties, also the root and the bark, and are used both internally and externally. The white guava is most esteemed for eating in the raw state; but the pulp of both varieties is used in the West Indies in the preparation of two kinds of preserve, which are known as guava jelly and guava cheese, and furnish a not unimportant article of commerce.

The dark red spherical, well-flavoured fruit of *Psidium Cattleyanum*, Sabine, has the size of a large plum, and on account of its purplish pulp is known as purple guava, and in Brazil a *araçaseiro do campo;* it is indigenous to Brazil and naturalized in China.

Psidium guineense, Swartz, is cultivated in the West Indies for its somewhat smaller, dark yellow and internally red berry, and the fruit of *Eugenia* (*Myrtus*, Sprengel) *pseudo-psidium*, Jacquin, is esteemed there under the name of *bastard guava*.

Psidium montanum, Swartz, the *mountain guava* of Jamaica, has a globular fruit, scarcely ½ inch in diameter, which, like the flowers, has a bitter almond odour. A species of St. Vincent, *Psidium Guildingianum*, Grisenbach,

with small berries, only ¼ inch thick, has in its habit considerable resemblance to *Myrcia coriacea* and *Pimenta acris*, but the rigid leaves are devoid of pellucid dots.

Campomanesia (*Psidium*, Aublet) *aromatica*, Grisebach, has yellow globular eatable berries, and a foliage of a balm-like odour. The similar fruit of *Campomanesia lineatifolia*, Ruiz et Pavon, is known in Peru as *palillo*, and that of *Camp. cornifolia*, Kunth, in New Grenada, as *guyavo de Anselmo*.

In this connection should also be mentioned the *rose apple* and *Malay* or *Otaheite apple*, which have been naturalized in the West Indian Islands, and there, as in tropical Asia, their native country, are highly valued on account of their agreeable taste and rose-like odour. The former, *Jambosa vulgaris*, De Cand., s. *Eugenia* (*Myrtus*, Kunth) *Jambos*, Lin., is a globular or oval yellowish or reddish berry, about 1½ inch in diameter; the latter *Jambosa* (*Eugenia*, Lin.; *Myrtus*, Sprengel) *malaccensis*, De Cand., is pear-shaped or top-shaped, 3 or 4 inches long, of a crimson or blackish-red colour externally, and with a white, juicy pulp.

The bark and leaves of both species possess strongly astringent properties, and the seeds are aromatic and acrid. The fruit of several other species indigenous to tropical Asia is employed there like those mentioned.

The jambolana, *Syzygium* (*Eugenia*, Lam., *Calyptranthes*, Wild.) *Jambolanum*, De Cand., is also naturalized in Jamaica and other West Indian islands. The dark red oval and somewhat curved fruit is of the size of a large cherry, has an astringent, acidulous taste, and is employed in gargles; the bark, notably that of the root, is astringent and aromatic. Several other species of this genus, mostly indigenous to tropical Asia, bear eatable berries.—*Pharmaceutical Journal*.

EXTRACT OF VANILLA.

BY GEORGE W. KENNEDY.

The object of the writer is to present a reliable formula, which has, in his hands, proved very satisfactory during the past eight or ten years that it has been used. Prior to that time I had experimented considerably with menstruums of various alcoholic strength, and also with mixtures containing glycerine. I obtained good results from some, but the formula I have adopted I prefer to all others, and am satisfied that even the inexperienced can manufacture a good preparation, provided they use a good quality of bean and carry out the manipulation properly. The formula does not differ materially from the many in general use, both as to alcoholic strength and the quantity of bean used, although some pharmacists use less than one ounce to the pint: but to insure uniformity throughout the country, I think that the strength indicated should be generally adopted.

For exhausting the vanilla, various writers have suggested simple percolation, repercolation, digestion—both with a cold and warm menstruum and either for a limited or an unlimited period—and prolonged maceration followed by percolation. The writer prefers simple percolation, which, of course, requires to be skilfully managed. Some writers have recommended strong alcohol as a menstruum. This, I believe is unnecessary, as it is a waste of alcohol, making the preparation more expensive without obtaining better results. I have found 50 per cent alcohol to answer the purpose admirably, and as vanillin, to which the odor is due, is soluble in this menstruum, it is, in my judgment, the most desirable one to use.

As there are many varieties of vanilla in the market, attention should be given as to its selection. A good quality, although perhaps decidedly more expensive at the outset, will be the cheapest in the end for preparing the extract. There is an inferior kind of Mexican vanilla sent into the market, cut up into small pieces of an inch or a little more in length, which consists of beans unfit to be bundled up, and is offered at the low price of $5 per pound. It is unwise to purchase vanilla in a broken condition. In the manufacture of an extract only a good quality of Mexican bean should be used, which has a peculiar, agreeable, characteristic odor of its own, whilst some of the other kinds have an odor resembling that of tonka, which, in my judgment, makes those varieties decidedly objectionable. You might almost as well use a certain percentage of tonka bean as the lower kinds of vanilla for the purpose of making a cheap flavouring extract. A preparation should be sold for what it is, and nothing else. If it contains tonka call it, say, compound extract of vanilla for flavouriug, or any other suitable name, but, above all, do not throw it upon the market as extract of vanilla. There are those people perhaps, though very few, who prefer the odor of tonka, which is due to coumarin, but for their use an extract of tonka could easily be prepared.

A short time ago I was offered, by a travelling salesman, a bean at $4 per pound. He stated for extract purposes it was just the thing, and was largely sold to ice-cream makers and others. They were about six inches long, bright brown in colour, quite dry and brittle, void of odor, and would remind one of a bean that had laid in alcohol for weeks, taken out and dried. Cheap and worthless extracts of vanilla appear to be largely sold, and perhaps mainly by grocers.

The formula proposed is as follows:—

Take of Good Mexican Vanilla .....4 oz.
Sugar (granulated).....4 oz.
Alcohol, water, of each a sufficient quantity.

Cut the bean transversely into small pieces, place the sugar and the cut bean into an iron mortar of convenient size, and reduce to as fine a condition as practical, after which moisture the powder with a mixture of alcohol and water in proper proportion, so as to obtain a menstruum containing not less than fifty (50) per cent of alcohol; then carefully pack the moistured powder in a cylindrical percolator, close the lower orifice with a cork, pour on more menstruum of the same strength (sufficient to cover the surface of the powder), cover the top of the percolator, and allow it to remain undisturbed for twenty-four hours; then remove the cork and permit percolation to proceed, not faster than at the rate of 40 drops per minute, and continue until four pints have passed, when the preparation is completed.—*American Journal of Pharmacy*.

THE CULTIVATION OF JALAP.

BY E. M. HOLMES, F.L.S.

In the last number of your valuable journal a remark is made as follows:—"From an analysis and valuation made of the root in India, there can be no doubt entertained as regards the commercial value of Ootacamund grown jalap." It is probably not generally known that the commercial value of a drug is to a certain extent dependent upon its appearance; and regarded from this point of view, the Ootacamund jalap might probably be improved in value by a little care in its preparation. When a new drug is offered in the London market, the wholesale druggists will not readily purchase it, unless it corresponds in appearance with that which they have been accustomed to buy, or unless it can be obtained at a lower price, while guaranteed by analysis to equal the best qualities met with in commerce. Thus if jalap grown in India can be sold in England at a price that will enable the manufacturer to prepare jalap resin or jalapin of as good quality as that obtained from Mexican jalap at a cheaper rate, he will buy it for that purpose, but he will not purchase the root to sell again if it differs much in appearance or colour from the ordinary drug. Now the samples of Ootacamund jalap, as well as those from Jamaica, which have been offered in this country, are usually in the form of slices, which are much whiter and more starchy-looking than the tubers obtained from Mexico, and have not the smoky flavour and wrinkled appearance of the ordinary drug.

These differences probably depend upon the mode of drying. In Mexico, owing to the wetness of the climate in the districts where jalap is collected, the tubers are generally hung up in a net over the constantly burning fire in the Indian's hut, and in consequence acquire a smoky flavour, and become slowly dried in an atmosphere that probably prevents fermentative changes. How far this process can be imitated on a large scale it is of course for those who cultivate jalap to determine. Mr. D. Morris, of Jamaica, in a letter received a few months since, informed me that he calculated that the artificial drying would add about 2d per lb. to the cost of production. This, however, would hardly be a consideration

when the crude drug is required for sale in that state. This gentleman appears to have paid considerable attention to the cultivation of the drug, and the following statements gathered from information communicated by him may have some practical value.

At first the jalap was planted among the cinchonas, but it was found to exhaust the soil too much, and was consequently removed. In the year 1880-81 the crop of Jamaica jalap amounted to 14,924 lb., and sold in the fresh state for £62 3s 8d. He found it impossible to dry the tubers, either whole or gashed, without the aid of artificial heat. They lost over 70 per cent in drying, so that it required nearly 1,800 lb. of green tubers to yield 500, lb. of marketable jalap. Some specimens of Jamaica-grown jalap received from Mr. Morris were carefully analysed at my request by Mr. T. Greenish, F.C.S., who found that the whole tubers yielded 9·13 per cent of resin while the sliced drug, dried without artificial heat, yielded 9·89 per cent of resin, and a specimen of India jalap contained rather less. Mexican jalap yields on an average 11 or 12 per cent of resin, but sometimes as much as 18 per cent. The percentage of resin in jalap root is often erroneously estimated at too high a rate by those unaccustomed to analysing the drug owing to the difficulty, without careful washing, of freeing the resin from adhering sugar; but in the analysis above quoted, especial care was taken to obviate this source of error. It would appear, therefore, that neither Jamaica nor India, as yet produce jalap equal either in percentage of resin, or in appearance or odour, to that of Mexico. According to the experiments of Professor Tichborne and Mr. Conroy,* the largest Mexican tubers are inferior to those of smaller size, the former containing often 25 per cent less resin, and more starch in proportion.

In its native country jalap grows in shady woods on the eastern declivities of the Andes, at an elevation of 5,000 to 8,000 feet, in regions where the rain falls almost daily, and when the temperature during the day ranges between 60° to 70° Fahr. It prefers a deep, rich vegetable soil. Where these requirements are met with, jalap may doubtless be successfully and profitably cultivated, although the demand for the drug will probably always be a limited one, as compared with cinchona bark —*Planters' Gazette.*

COFFEE MANURES.

Whilst there is still great difference of opinion amongst experienced planters as to the best description of artificial manure for coffee, there are very few indeed who do not admit that high cultivation is absolutely necessary in order to sustain the vitality of the trees, and enable them to resist successfully the attacks of disease or the effects of continuous crops. It will therefore be interesting to give some account of the special fertilizers for coffee manufactured in this country. Three makers have established a high reputation for themselves in this particular line, and we shall refer to each in turn. The writer of a pamphlet on Odam's Special Manure for coffee says:—"The best results are obtained by the application of manures which contain not two or three ingredients of nutrition only, but a variety of the fertilizing elements of plants, and these in a natural form in order to the proper nourishment of the tree and its maintenance in full bearing. All merely nitrogenous manures wholly in a soluble form should be avoided, such manures being stimulants only, the free use of them scourging the land and leading to disease, and at best a premature exhaustion of the tree.

Old estates, especially, are deficient in organic matter, and for successful cultivation in such cases organic matter containing nitrogen must be supplied. Odam's Special Manure may be applied in conjunction with cattle dung, rotten grass, leaves, pulping, &c. Those applications are conducive to the preservation of moisture in the soil, which is of the utmost importance for the continuous growth of the coffee tree, and much promotes the proper assimilation of the ingredients of the fertilizer employed.

This manure will be found suitable for either plantation or native coffee.

Those who may be in the habit of using bone dust will find much advantage from a mixture of that article and Odams' Special Manure, instead of applying bone dust alone.

Mr. John Hughes, F.C.S., has reported favourably of the compound above referred to, and furnished the following analysis:—

Moisture	15·10
*Water of Combination and Organic Matter, including Salts of Ammonia	26·92
Monobasic Phosphate of Lime	14·64
(Equal to Tribasic Phosphate of Lime rendered soluble by acid)	(22·93)
Insoluble Phosphates (Bone)	6·48
Sulphate of Lime	22·15
**Alkaline Salts and Magnesia	12·20
Insoluble Silicious Matter	2·45
	100·00

*Containing Nitrogen...	*Nitrogen soluble equal to Ammonia ...	3·27
Equal to Ammonia ...	Nitrogen insoluble equal to Ammonia ...	·69
**Containing Potash ...	... ...	
Equal to Sulphate of Potash...	Total Ammonia ... ...**Containing Potash ..	3·96 5·55

Messrs. Arnott Bros. & Co. is one of the oldest firms that have devoted attention to Special Manures for the leading tropical products, and for many years past the "Raw Bone Super-Phosphate Manure" and "Ammonia Phospho Coffee Manure" have been known and appreciated in Ceylon and other producing countries. Recently, however, another speciality has been added to the list in the shape of "Anti-Vastatrix Fertilizer New Leaf Disease Manure," regarding which the manufacturers say—It is the only Fertilizer, so far, that has really proved of any effect in subduing this disease, and it is fully protected under our Registered Trade Mark.

This Manure should be applied at the rate of about four cwt. per acre, and as a large proportion of its components are readily soluble in water, it should be well mulched, which will keep it at the rootlets of the trees, encourage its absorption, and not allow it to be so easily washed away in heavy rain.

Messrs. Ohlendorff, whose dissolved Peruvian guano has obtained world-wide repute, have also since 1874 been making a concentrated coffee manure which they describe as follows:—

This manure, which is styled Ohlendorff's Guaranteed Coffee Manure, is prepared by us, and sold of uniform strength, guaranteed to contain nitrogen in various stages of combination, equal to 4 per cent non-volatile ammonia, 27 per cent bone phosphate of lime, 20 per cent alkaline salts, including 5 per cent potash. In a fine, dry, powdery condition.

The phosphates we guarantee to be present in the shape of bone, or in organic forms, to the entire exclusion of cheap and ineffective mineral phosphates. Of the 27 per cent of phosphates, 5 to 6 per cent are rendered soluble in water, and the rest is present as insoluble bone phosphate of lime, in a state of combination sufficiently available to support the healthy growth of the trees, and to promote a large yield of well-matured coffee-berries.

Alkaline salts, or salts of potash and soda, which we are informed are generally deficient in Indian coffee soils, play an important function in coffee cultivation, and the supply of potash in a proper state of combination, hitherto, has not received the attention which it deserves.

In addition to above constituents our coffee manure contains magnesia, lime, soda, silica, &c., and in fact all the mineral constituents found in the ash of the coffee-berry. Thus our coffee manure embodies all the organic and inorganic elements of nutrition, essential for the coffee tree. —*Planters' Gazette.*

A GLIMPSE AT WHAT MIGHT BECOME A NEW INDIGO COUNTRY.

It was at the end of the last, and at the beginning of this century, that the indigo industry in India took an immense start under the enterprising energy of European settlers. The stock from which they obtained their plant, was that of the Indigofera tinctoria, "anil" and "disperma,"

* *Pharmaceutical Journal*, October 15, 1881, p. 324.

natives of Hindustan, and such as had produced the "Indicum" known by the Romans and the Greeks, and before them by the Egyptians, witness the blue wrappers of the mummies. From this same stock had also been derived the plants which the Spaniards found advantageous to introduce into Central America, notwithstanding the presence there of a biennial indigenous indigo plant, producing indigo of a fair quality, but yielding only half the quantity which is given by the cultivated species. At that time the cultivation of indigo was carried on by the Portuguese in the north of Brazil, also on a small scale by the European planters of Guiana and the West Indies, but it was very extensive in all the Spanish colonies of Central America, laying between the equator and the 20th degree of north latitude. A race for competition between the American and the East Indian planters, immediately ensued; the great facilities and cheapness of labour in India, the care brought into the process of manufacture, as well as the energy of the English and French planters, (a great part of the factories in Lower Bengal was at one time in the hands of Frenchmen or French creoles from the Mauritius) gave them an immense advantage over their antagonists, and after the declaration of the independence of the Spanish colonies, and the disturbances that followed, the production of indigo from America fell considerably, and in many provinces ceased entirely. At present the yearly production cannot be calculated to reach above 15,000 maunds, and nearly the whole of that quantity comes from the States of Guatemala and San Salvador. In Java under the monopoly system of the Dutch, the indigo industry is kept under limits, probably because the Governors at Buitenzorg find it pays them better that other crops should be cultivated. The average yearly outturn is not above 20,000 maunds. In India setting aside the Madras Presidency, where a limited cultivation is still carried on by natives in the Cuddapah and adjoining districts, and by Europeans in the northern part of the presidency towards Bimlipatam and part of Ganjam, the whole of the industry is carried on in the Bengal Presidency, between the 23° and 27° of north latitude, and in the vicinity of the river Ganges and its tributaries.

The indigo industry of India, notwithstanding the large capital at stake is, for the greater number of planters after all, but a precarious one. With the exception of a few favored concerns that have abundance of land, held at cheap rates for the cultivation of the plant, and that are besides situated in thickly populated districts, the greatest part of the factories suffer from the want of the one or the other. The high rates of interest charged, the commissions to agents and brokers, swallow but too often all their profits. This may not be a bright picture, yet, it is, but too correct. The American production as stated before, is almost entirely reduced to that of the States of San Salvador and Guatemala, where it attains about 15,000 maunds yearly. Now, if notwithstanding the endemic state of revolution in which these States have existed for the last fifty years, the indigo industry retains there, still a certain position, it is not owing to any greater degree of energy of the people, nor to more facilities for labour, nor to the abundance of capital; on the contrary, the people are wanting in the commercial energy which remains powerful under English rule; labour is very scarce and expensive, as proved in the case of the new Panama Canal scheme, and last of all, the republics of San Salvador and Guatemala are more or less bankrupts, and have been in that state for years, so that capital cannot be said to be plentiful—no, none of the above considerations have any force, it is simply because the plant introduced by the Spaniards from the East, has under the influence of soil and climate, acquired certain advantages and qualities which the mother stock does not possess. It is stated by travellers and colonists, and it is recorded from reliable commercial sources, that the produce of an area of indigo in Central America, is greatly in excess of what is obtained in any other country in the world. The production is estimated at from 60 lb. to 65 lb. per acre, and this is from 250 to 300 per cent more than the produce of indigo land in Tirhoot or the Benares districts, where the yield is the largest in India.

If added to this, it is noted that the indigo plant in Central America will bear during three years, and give two cuttings each year, altogether six cuttings, whilst the plant in India, gives at best two cuttings only, the secret is at once obtained of the vitality of the indigo industry in San Salvador and Guatemala.

Looking at the map of India, we see at once that the country which resembles most the configuration of Central America, is the southern part of the Tenasserim provinces in British Burmah—situated between the 10° and 15° of north latitude, as the indigo districts of Central America are; it is like those districts also, between two seas, the gulf of Bengal and the gulf of Siam taking the place of the Carribean Sea and the Pacific Ocean, its chain of mountains divide the country, and the drainage is effected in the same way. Last, it possesses a similar climate, the moist equable temperature of Central America. If new fields had to be searched for the extension of the indigo industry in India, the most likely place of success would probably be the country indicated. The great disadvantage would be the want of labor, which would have to be imported, and it is likely in that case, that Chinese labour, easily procurable within a short distance, (Penang or Singapore) would prove the cheapest in the end. It would certainly not be dearer than Central American labour. —*Indigo Planters' Gazette.*

WHITE ANTS.

The following interesting information regarding these industrious but destructive animals is taken from the *Asian*, and is condensed from two letters from different sources which appeared in that journal:—

For a year or two I have been watching the effects of white ants on our forests. I was first particularly struck with their work two hot seasons ago. The ground was thickly strewn with dry leaves, and I was getting nervous about fire conservancy, when we had a fall of rain; a few days after the rain by far the greater proportion of the dry leaves had gone. The natives told me that the white ants had eaten them, so I examined the ground then, and a few times since after the rain, and now I believe that what I was told is correct, and I begin in many ways to consider that white ants are very useful to foresters. Mr. Darwin's very excellent book on worms shows the vast amount of cultivation these small animals can accomplish. Worms in certain places throw up large castings in this country, but up to the present time I have only observed them in low-lying moist ground. In our forests I have seen that white ants do more than any other insects in removing dead leaves, twigs, wood of all sizes, and grass. As far as I know, the food of white ants must be dead before they can eat it. They are often found eating the bark of trees, and our Indian *malis* are very careful to brush off their galleries, but if left alone I don't think they would do any harm. I have under my charge some forests that have not been burnt for six years, and one for seven years. I notice that in these forests the white ant is everywhere, but I cannot as yet discover any damage that he is doing. The young Sal that were annually burnt have now strong healthy shoots, in some instances even 25 feet or more high. The old stem of some is still plainly seen, and I notice that it is only on the lower part of the tree that the white ant finds work to do; the shoots at the top of the old stem are never touched. On many other trees I have brushed off the galleries of the white ant, and seen a new green healthy bark forming underneath. Also in many instances I have seen a healthy vigorous tree growing untouched in a white ant hill, apparently doing uncommonly well in that position.* Many of the true ants remove dead vegetable matter I know, and also many other insects. The white ant is not an ant, as, no doubt, many of your readers already know; it belongs to the family of "Neuroptera," the type of which order are the Dragon Flies. The true ants belong to the family of "Hymenoptera," and in this family are included also the bees and wasps. In my opinion the white ant does wonders in keeping the surface soil of our Indian forests in a healthy state. Every leaf, every dry stalk of grass, and every twig are

* It is notably so with the cinnamon bushes in Ceylon which flourish in pyramids of earth inhabited by the termites. But it is now beyond doubt that they destroy the living tissues of tea in India and of cocoa (cacao) in Ceylon.—ED.

eaten by them, and to accomplish its work in safety, it covers the food it is about to eat with galleries of clayey earth. This earth is brought up from the sub-soil, and so it goes on day after day, and year after year, bringing up the sub-soil to the surface. In one year alone this becomes a considerable layer averaging fully the one-eighth of an inch I should say, but probably more. Mr. Darwin's book, already referred to, shows the immense amount of work that worms can do, and this is equalled, if not surpassed, by white ants, where they are numerous. Mr. Darwin tells us that in certain localities worm castings are not found, but the white ant is nearly everywhere. As a destroyer of man's labors undoubtedly the white ant deserves much abuse; but on the other hand, I am sure he is a most useful insect. How often do we see in notes and official reports on agriculture or in reviews on them, people wondering how the plains of India are able to keep on growing crops without manure and deep ploughing; but I have seldom seen any one suggesting that insects are the principal cause of the fruitfulness of the land. Insects, sun, rain, and a little cultivation at the time of sowing, and weeding afterwards, are all that is necessary to get a crop, not a bumper crop but a moderate one. For eleven years all through the cold season I have been in the habit of eating my breakfast whilst lying on the ground, and I have invariably watched the insects. Almost everywhere the galleries of the white ant are to be seen. There he is always at it, bringing up the sub-soil, and converting dead vegetable matter into manure, and that is why the habit of leaving a field fallow has such good effects, for then the insects are able to go on undisturbed at their work In a forest they have it all their own way, barring the birds, beasts, and other insects that feed on them. The white ants' numbers are, all sportsmen know, greatly reduced by a few sloth bears, for they are very fond of them, and pheasants, partridges, and many other birds eat them, also several kinds of insects.* Besides the food already mentioned, white ants are very fond of elephant's dung and cow dung. The galleries are useful to them as a protection from the sun, and also from other insects. How many kinds of white ants we have in the forests of India I don't know as yet, but I think that there are two kinds, if not more. I am not aware whether it is known or not, that white ants are able to extract enough moisture from their bodies for repairs to their nests. I have seen a large piece of an ant hill repaired by them in dry weather very quickly, when they were in the piece that had been broken off. In that instance they appear to have thought that they were in their own nest, and not in a piece of it only, and they had no means of communicating with the ground beneath, so they must have formed the moisture used by themselves. In the case seen by me the covering made over the broken part was a very thin one.

I shall be very glad to hear of any book on the white ants of India, as I wish to find out all I can about them. All the books I have read treat only of white ants of other countries, and then only abusing them as destroyers, and never looking on them as of any use. I am firmly convinced that they are very useful in many ways in India, and so are many other insects. We are all of us apt to overrate our own works, and underrate the works of others, and especially the works of insects; but Mr. Darwin has shown us what worms can do so thoroughly, that I have no doubt many other small animals will be studied now. I don't pretend to be a naturalist, and shall be very much obliged to any one who will correct me when I am wrong, and also to any one who will send me any information on white ants, or if any one will recommend any books on insects that are wood-eaters.

White ants (*Termes*) belong to the order *Neuroptera*, and with the true ants (*Hymenoptera*) wasps, bees, and hornets are, I believe, the only insects that form perfectly organised societies. Herewith M. P. Huber's observations on the subject:—"The great end of the societies of insects being rapid multiplication of species, Providence has employed extraordinary means to secure the fulfilment of this object, by creating a particular order of individuals in each society, who devote themselves wholly to labour, and thus absolve the females from every employment, but that of furnishing the society, from time to time, with a sufficient supply of eggs to keep up the population to its proper standard. In the case of termites, the office of working for the society, as these insects belong to an order whose metamorphosis is *semi-complete* devolves upon the larvæ—the neuters, unless these should be the larvæ of males, being the soldiers of the community. From this circumstance perfect societies may be divided into two classes—the first including those whose workers are larvæ, and the second those whose workers are neuters. The white ants belong to the former class, and the social *Hymenoptera* to the latter." The societies of these *Neuroptera* consist of five descriptions of individuals—workers or larvæ, nymphs or pupæ, neuters or soldiers, males and females.

(1.) *The workers or larvæ* are the most numerous, and at the same time the most active of the community, upon whom devolves the office of erecting and repairing the buildings, collecting provisions, attending upon the female, conveying the eggs when laid to the nurseries, and feeding the young larvæ till they are old enough to take care of themselves. They are distinguished from the soldiers by their diminutive size, by their round heads, and short mandibles.

(2.) *The nymphs or pupæ.*—These differ in nothing from the larvæ, and probably are equally active, except that they have the wings folded up in cases (*pterothecæ*).

(3.) *The neuters.*—These are much less numerous than the workers bearing the proportion of one to one hundred, and exceeding them greatly in bulk. They are also distinguishable by their long and large head, armed with very long subulate mandibles. Their office is that of sentinels, and when the nest is attacked, to them is committed the task of defending it.

(4 & 5).—*Males and females*, or the insects arrived at their state of perfection. There is only one in each separate society; they are exempted from all participation in the labours and employments occupying the rest of the community. Though at their first disclosure from the pupæ they have four wings, they soon cast them, but they may be distinguished from blind larvæ, pupæ and neuters by their large and prominent eyes.

The first establishment of a colony takes place thus:—In the evening, soon after the first tornado, which at the end of the dry season proclaims the approach of the ensuing rains, these insects, having attained to their perfect state in which they are furnished with two pair of wings, emerge from their clay-built citadels by myriads and myriads to seek their fortune. Borne on these ample wings and carried by the wind, they fill the air, entering houses, extinguishing the lights, &c., &c. The next morning they are discovered covering the surface of the earth and waters, and having lost their wings, which are only calculated to carry them a few hours, are only capable of crawling on the ground. In this state they are destroyed wholesale by men, birds, reptiles, &c. "The workers, continually prowling about their covered ways, occasionally come upon some of these, and being impelled by instinct, they immediately elect a king and queen, or rather father and mother, of a new colony.* The workers, as soon as this election takes place, begin to enclose their new rulers in a small chamber of clay, suited to their size, the entrances to which are only large enough to admit themselves and the neuters, but much too small for the royal pair to get through, so that their state of royalty is a state of confinement all their lives. The care of feeding the queen and her companion devolves on the larvæ, who supply them with food, and as she increases in dimensions they keep enlarging the cell. When the business of oviposition commences they take her eggs from her, and deposit them in the nurseries. She now continues to grow till her bulk equals 20,000 or 30,000 workers, and gives sometimes from sixty eggs a minute, or eighty thousand and upwards in twenty-four hours! They live two years in their perfect state. When the eggs are hatched they are provided with food and receive every necessary attention till able to shift for themselves. The royal cell has, besides some soldiers in it, a kind of body guard to the royal

* We have seen the common grey Ceylon squirrel feasting on white ants which had covered their galleries up the stems of coconut palms. Fowls are exceedingly fond of them as food.—ED.

* This statement about only one *male* in a nest is quite new to us. Our impression was that, as in the case of bees, there were many male insects although only one "queen."—ED.

pair, and the surrounding compartments contain always many labourers and soldiers."

I had no idea white ants could produce any sounds, but from the following it appears they can:—"In the process of building or repairing each labourer carries in his mouth a mass of mortar which he sticks on to its proper place. When engaged in this work all the soldiers retire, except one or two, who saunter about amongst them, but never assist. Every now and then this overseer, by lifting his head and striking with his forceps upon the wall of the building, makes a particular noise, which is answered by a loud hiss from all the labourers, and appears to be the signal for despatch; for every time it is heard they may be seen to redouble their exertions. On the nest being attacked, in rush the labourers, and out march the military, who again retire when all is quiet." Again a species larger than *Termes bellicosus* called the *Termes viarum*, makes the same sort of hiss according to Mr. Smeathman. He describes having heard a loud hiss like that of serpents, but this statement appears to me doubtful.* I would advise enquirers to get Kirby and Spence's Entomology. In it they will find long and very interesting accounts of the ways, habitations, food, &c., of insects. The book is an old one, but contains a vast amount of information.—*Indian Agriculturist.*

TOMATO SEEDS.—These are furnished with an abundance of a slimy mucilage, which many find it difficult to remove. If the seeds are dried as they are taken from the fruit, they will adhere in a mass, and be difficult to separate. Remove the masses of pulp which contain the seeds, place them in a bowl and cover with water. Let them remain where they can be examined daily; fermentation will soon take place, and when the seeds are found to be free from the mucilage, wash and dry them. This will not injure the vitality of the seeds, if the fermentation is stopped as soon as they are clean.—*American Agriculturist.*

LIME APPLIED TO SOILS, naturally destitute of it, supplies an essential element of plant food. In most cases, however, the good effects of this substance is due to the chemical action which it exerts in the soil. It renders available the plant food in the soil, without supplying it. Liming is therefore a stimulating process, and can only be practised with success upon soil that is already rich in plant food. Freshly burned lime is the most effective, as it quickly and thoroughly reduces organic matter to an available form. Ground limestone, so highly recommended, is of no special value, except on clay soils, or those destitute of lime, where it acts as a direct fertilizer, and not as a reducing agent.—*American Agriculturist.*

CINCHONA BARK.—In some "Notes on the Pharmacy of Cinchona," Mr. R. W. Giles called attention to the unsatisfactory results that have followed the "fearful deterioration of Calisaya bark," both pharmacy and medical practice having been prejudiced through the consequent substitution of quinine for pharmaceutical preparations of the bark. He recommends that all pharmacists should keep in stock Indian or other non-official bark of sufficient alkaloidal value, and that when opportunity offers they should educate the medical profession to the use of it. He considers that the standard adopted for the cinchona of pharmacy should be an alkaloidal and not a quinine standard, that it should be a mean and not an extreme one, and that it should admit barks from all sources. Further, he described a process for the determination of the alkaloidal value of cinchona bark which, he said, though simple and easy of manipulation, gives results near enough for pharmaceutical purposes. He expressed a preference for a fluid extract as a pharmaceutical preparation, but said that a fluid extract of cinchona worthy of its name was still a desideratum. In the discussion of this paper, Mr. Welcome recommended that the standard of a pharmaceutical bark should be fixed at 2 per cent of quinine with a proper proportion of the other cinchona alkaloids. Mr. Southall spoke favourably of the decoction, which he said was largely used in the Birmingham district, and Dr. Symes said it was also a favourite preparation in Liverpool. On the other hand, Mr. Ekin reminded the Conference that he had found the decoction to be the preparation weakest in alkaloid.—*Pharmaceutical Journal.*

*The explanation may be found in the fact that snakes often inhabit the galleries made by white ants.—ED.

MANGROVES.—Twenty-four young Mangrove trees (Rhizophora sp.), of three different varieties, have recently been brought home in good condition by Lieut.-Colonel E. S. Berkeley, and are now in the gardens of the Royal Botanic Society of London, Regent's Park. The Mangrove is found in abundance on the shores and creeks of tropical islands, and at the mouth of large rivers in the East. The tree is very valuable as fuel for river steamers, being as a fuel next to coal in heat-giving properties; the bark is utilized for tanning leather, and is also said to furnish a febrifuge, which, if true, is very curious, as a Mangrove swamp is a fertile source of fever.—*Gardeners' Chronicle.*

REPORT ON THE DIFFERENCES BETWEEN THE ESSENTIAL OILS OF CINNAMON AND CASSIA, BY MR. A. H. JACKSON.—The reporter stated that, tested from a physical standpoint, the oils possess distinctive and characteristic odours, and that the cinnamon oil has a more fiery taste than the cassia, but that neither the relative densities nor the refractive energies are sufficient guides in distinguishing mixtures of these oils, though the density of the oil of cassia was found to be somewhat greater than that of the oil of cinnamon. The chemical examination seemed to show that the constituent or constituents in which the oils differ from each other are present only in extremely small proportion.—*Pharmaceutical Journal.*

PETROLEUM AS AN INSECTICIDE.—I can fully indorse all that Mr. Duffield states (p. 363) as to the efficacy of petroleum as a remedy for many of the insect pests with which gardeners are troubled; and further, I would warn all those who are not practically acquainted with it as an insecticide to be extremely cautious how, when, and where they use it before they are better informed respecting its damaging properties, as the remedy may prove far worse than the evil, as the following instances will show. My own and first aquaintance with this oil as an insect killer dates back to some fifteen or sixteen years ago. Our plan of using it is to put two wineglassfuls of oil with four gallons of water, and mix it precisely in the same way as that recommended by your correspondent at p. 363. For green or black, or any kind of scale, I don't know of anything cheaper or better. This much, however, I feel compelled to say—viz., do not use it too often early in the spring, when the foliage is young and tender, or the consequences will be that the young leaves will fall off before they are half grown, especially in the cases of Peaches and Nectarines—in fact, I would not recommend its being used on anything when the foliage is young and tender, but when it is fully developed little or no injury will result.—H.—*Gardeners' Chronicle.*

LATENT VITALITY OF SEEDS.—Messrs. Ph. van Tieghem and Gastou Bonnier have been making some preliminary experiments to ascertain the effects of different conditions on the latent vitality of seeds. On January 9, 1880, several packets of seeds supplied by Vilmorin were divided each into three equal parts. One portion was exposed to the free air, but screened from dust; another portion was put into closed air, securely corked up in a tube; whilst the third was placed in pure carbonic acid. At the end of two years the seeds were taken out and weighed, and afterwards sown. With regard to weight all the seeds exposed to free air increased in weight. Thus, for example, fifty seeds of the common Pea were found to have increased about $\frac{1}{12}$ of their original weight; and fifty seeds of the French Bean about $\frac{1}{56}$ of their original weight. The seeds confined in closed air increased in weight, but infinitely less than those exposed to free air, and the increase in some instances was so trifling as to be hardly measurable. Thus fifty Peas increased about $\frac{1}{780}$ of their original weight; and fifty Beans about $\frac{1}{1190}$ of their original weight. As for seeds placed in pure carbonic acid, they did not vary half a milligramme from their original weight. The following are two examples of the comparative germination of the seeds, the conditions being as near as possible exactly the same:—

Peas left in the free air, 90 per cent germinated.
" " " closed air, 45 per cent germinated.
" " " pure carbonic acid, 0 per cent germinated.
Beans left in the free air, 98 per cent germinated.
" " " closed air, 2 per cent germinated.
" " " carbonic acid, 0 per cent germinated.
—*Gardeners' Chronicle.*

THE TEACHING OF FORESTRY.

LECTURE BY COLONEL G. F. PEARSON.

As a proof of what has been already effected in India by the forest officers educated in the Continental schools, I may mention that in that country there are at the present date 9,820,000 acres of reserved forests, and 2,493,000 of which are protected from fire, as well as cattle and sheep grazing, and consequently are now in a condition to reproduce themselves under the natural system; and as perhaps, the most convincing proof, from a practical point of view, of the value of the system, I may add that the forest revenue of India, which in 1870 was only £357,030, with a net revenue of £52,000, in 1880 reached £545,000, with a net revenue of £215,000—that is to say, that the revenue had increased 56 per cent, while the charges had only increased 8 per cent.

In South Australia, a serious commencement has been made in the right direction also. By an Act passed in 1873, the sum of £2 per acre is paid to landowners, in certain districts of the colony, to form plantations of trees. In 1875, a Forest Board was constituted as certain districts of the colony were formally defined as forest reserves. In 1878, a Forest Act was passed and a Conservator of Forests. (Mr. Brown) was appointed. Last year about a quarter of a million trees were planted out, and the forest revenue amounted to £6.517, of which £1,380 was for timber sold, against an expenditure of £6,200.

If, then, so much has been done by the Indian and Colonial Governments to secure the future of their forests, can nothing be accomplished at the head-quarters of the Empire? This is the question now before us, and I trust that it may be answered by instituting a course of instruction which may eventually develop into a forest school for Great Britian.—*Society of Arts Journal.*

ARROWROOT MANUFACTURE IN QUEENSLAND.*

The machinery used for the manufacture of arrowroot is simple in the extreme, and is chiefly manufactured on the place, the shafts, pulleys and engine work being, of course, foundry made. The first process shown was the roots being tipped by two boys into a long trough, through the length of which a shaft slowly revolved, and by means of wooden projecting pegs the dirty roots were stirred up and so cleaned, there being a constant stream of water running through the trough. These revolving pegs have a screw pitch, so that the roots are gradually moved towards the far end of the trough, where they are caught up by a sort of bucket pump which elevates them some 12 feet and drops them regularly into a hopper. As they fall to the bottom of this they meet the grater, which is a drum of perforated galvanised iron driven at great velocity. A small stream of water pours into this all the time, and the roots are quickly grated up into a brown coloured pulp. This mass of fibre and pulp falls into a cylinder of perforated iron, about 9 feet long and 2 feet in diameter; through the length of this runs an axle on which are two beaters like the drum of a threshing machine; these smash up the fibrous pulp, exposing it to the action of the water, so as to enable all the starch and fine pulp to be washed out and squeezed through the perforations of the cylinder, while from the one end is discharged a constant stream of the dirty looking fibrous refuse. A stranger looking at the process at this stage would think it utterly impossible that the white arrowroot of commerce could be the result of such an unpromising material; however, water works wonders, and an abundance of pure, soft water is essential for the successful manufacture of arrowroot. The finer pulp, as squeezed through the perforations of this cylinder, is received in a precisely similar one below; here again the mass, now only pulp, is beat up; but the perforations around this second drum being very small, only the starch and dirty looking water passes through, the pulp being again discharged from the cloaca at the end. The stream of water and starch pouring from these cylinders is received in troughing, extending for 100 feet around the shed, and, as it runs along, the starch, being heavier than the water, all sinks to the bottom and the water runs away. So far the work goes on automatically, no one but the two boys throwing in the roots troubling themselves about it. But towards the end of the day the stream of water is stopped, and the arrowroot starch scraped up out of the trough, where it has accumulated in a layer some inches in thickness, and is placed in large vats or tubs, all ranged in regular rows. Before being put into these tubs it is passed through fine muslin sieves, and at the same time another stream of water is turned on. These fine sieves effectually clear it of any foreign matter, and it settles by the morning at the bottom of the vats, clean and white as snow. The water is drained from it, and the starch put into a centrifugal machine exactly similar to that what is used for sugar; this soon forces out the surplus water, but perfect dryness is essential to its keeping qualities, so it is now carried to the drying room, which is some 60 feet long by 12 feet wide. Round the whole length of this runs a flue heated by a special furnace, and over this are shelves of galvanized wire netting; on this netting is placed calico, and on this is spread out the starch. In this hothouse the moisture is quickly evaporated, and the arrowroot becomes crisp and grain-like. On fine days it is spread out in the sun on similar wire stages. All operations are now finished, and the flour is stowed away in bins in the storehouse, and there made up into the packets usually seen in the shops. For this work-women are employed, and smart hands can earn as much at this employment as their husbands are doing at the rougher work of the mill.—*Pharmaceutical Journal.*

THE SQUARE BAMBOO.

One of the chastest and most elegant ornaments provided by Chinese ingenuity for the library or study, consists of bamboo boards, the ground being elaborately carved in fretwork, and inscribed with characters, generally quotations from the classics, cut from the wood of the same plant. They are to be obtained from the Chinese in Shanghai, and are valuable by reason of the peculiar character of the material from which they are made. Bamboos are divided into a large number of species, and well repay the study of those who take an interest in botanical researches. There is one sort of a remarkably unique character, called the "square" bamboo, specimens of which have, we understand, been forwarded by Dr. Macgowan at Wenchou to the United States Consul General at this port, together with a sample of the ornament above described, the device in this instance, however, consisting of a representation of the bamboo itself. Some of the plants received from the Doctor are destined for the Park at San Francisco, while others of the same nature are intended for the Public Garden at Shanghai. The following description of this novel-shaped product of the vegetable kingdon will, we think, be found of interest by our readers.

There is no plant except cereals proper which has received so much attention as this graceful grass. Early Chinese botanists enumerate seventy varieties of the bamboo, but if quest were now made in local gazetteers, that number would be found greatly augmented. They describe the bamboo as dioecious. Pre-eminence is assigned to the square variety of this most useful as well as ornamental plant, which has been a favourite in Imperial gardens whenever its acclimitisation has been effected in the North. The Emperor Kao Tsu once inquired of his attendants who were planting bamboos, concerning the various kinds. In reply he was informed respecting several remarkable species. Chekiang in particular furnished one that was an extraordinary curiosity, in that it was square, and for that quality and its perfect uprightness was much esteemed by officers and scholars. They also told him that it was used for many purposes of decoration and utility, including, among others, that of being made into ink-slabs. Subsequently specimens were obtained, polished, and sent to his Majesty who thereon signified his respect for the article by rubbing ink with his own hand on the inkstand, and inditing an essay on the curiosity. In 650 A. D, the reigning Emperor sent a eunuch to Chekiang to obtain specimens for the Imperial Park. Besides being furnished from scattered portions of this province, it is found in Honan, Szechuen, Yunnan, and Hunan; in the latter province it appears to present its peculiar characteristic in a marked degree, being as square, with corners, and as well defined

as if cut with a knife. The Chekiang species have slightly rounded corners, and moreover they are more slender, being used only as pipe-stems, whereas the western kind is large enough to serve as staves for the aged. In its early stage of growth the square bamboo is nearly round, assuming the anomalous figure it afterwards presents as it advances towards maturity. Like several other kinds of bamboo it is thorny, abounding in small spines. If we may credit accounts which have reached China from Western Turkestan (Ta-yuen), there is or was produced in that region a square bamboo which is a curiosity of a curiosity. The Prince of that country possessed and highly prized a square bamboo, on the faces of which were eyes, beard, and teeth. Art no doubt contributed to the production. There are considerable varieties in the colour of bamboo,—white, yellow, reddish, purple and black. Besides being ornamental, it is useful, very pretty chairs being made of it. A native writer says of this plant that it "injures its mother," which means that its shoots must not be planted near the parent clump. In mentioning these curious bamboos, we must not forget the most useful description of all. We refer to what is generally known as the "hair" bamboo, the shoots of which constitute an excellent esculent, which is largely exported from the neighbourhood of Wenchou; the bearded appearance of the shoot giving it the hirsute designation. It is not like the square bamboo, which is adapted to limited areas only, but it will flourish almost wherever there is a due amount of heat, moisture, and a fertile soil. The uses of this kind of bamboo have been often described, but there is one purpose to which it is applied, and at Wenchou only, and therefore but little known. It is rendered plastic by being boiled half a day in potash and lime; the alkalies having done their work, a slit is made in the cylinder (which is of any required length, usually a foot), and it is then pressed out into a sheet form by heavy stones. These sheets of bamboo, which are sometimes a foot in width, are then carved, cutting them through, and in this way are formed representations of flowers, birds, various forms of characters in verse, and the like, which, glued to delicate filagree work of bamboo, and framed, make the unique and elegant pictures to which we have referred above.—*North China Herald.*

NEW DRUGS INTRODUCED DURING THE LAST TEN YEARS.

BY FRED. KILMER.

At a meeting of the American Pharmaceutical Association, held in 1880, at Saratoga, Mr. Jas. G. Steele, of California, exhibited about fifty specimens of California plants, some of which have become of some note, a list of the same is appended:—

1.—Alder Bark. *Alnus Oregona.* Tonic and astringent. Used for lotions in cases of sore mouths, ulcers, &c. 2.—Ava Kava Root. *Macropiper methysticum.* Used with success in gonorrhœa, gleet, gout, rheumatism, &c. 3.—Barberry, wild or holly-leaved, of *California. Berberis B. aquifolium.* Part used, the root. Tonic and alterative. Used in cancer, intermittent fever, and syphilis. Samples sent of entire plant of *B. aquifolium*; also of *B. repens*, the root of which is sometimes substituted for that of the former. 4.—Buckeye Bark. *Æsculus Californica.* Tonic, astringent, and antifebrile. 5.—Buckthorn Bark of California. *Rhamnus crocea.* Tonic, alterative, and laxative. 6.—Butterfly Plant. *Bahia arachnoidia.* Tonic, expectorant, diaphoretic, and alterative. 7.—Cascara Sagrada. *Rhamnus Purschiana.* Seven samples of the bark, from as many different localities, all more or less differing in appearance, but identical in therapeutic effects. Tonic and laxative. Used with success in dyspepsia, torpid liver, habitual constipation, piles, &c. 8.—Canchalagua. *Erythræa venusta.* Antifebrile and an aid to enfeebled digestion and impaired nutrition. A bitter tonic. 9.—Cedron Seeds. *Simaba Cedron.* Powerfully tonic and antiperiodic. Antidote to hydrophobia and the bites of venomous serpents. 10.—Copaique Bark. *Croton superosum.* Bitter tonic and antiperiodic. 11.—Damiana Leaves. *Turnera aphrodisiaca.* Aphrodisiac, tonic, and laxative. 12.—Durango Root. *Triecrastes glomerata.* Balsamic, tonic and stimulant to the circulatory system. 13.—El Gobernador. *Larrya Mexicana.* Balsamic, tonic, alterative, and laxative. 14.—Eucalyptus Leaves. *Eucalyptus globulus.* Tonic and antifebrile. Used in fevers, kidney diseases, catarrh of the bladder, and in diseases of the lungs and air passages. 15.—Garrya Bark. *Garrya elliptica.* Properties similar to the Garrya Leaves. 16.—Garrya Leaves, or California Quinine Bush. *Garrya Fremontii.* Bitter tonic, stimulant, antimalarial, and sedative. 17.—Ginger Leaf. *Eremocarpus setigerus.* Stomachic, tonic, carminative, and febrifuge. 18.—Grindelia. *G. robusta.* Expectorant, demulcent, and tonic. Used locally for the cure of "Poison Oak," 19.—*Grindelia Squarrosa.* Useful in malarial diseases, enlarged spleen, &c. 20.—Kidney Root. *Baccharis pillularis.* Balsamic, tonic, and stimulant to the kidneys and bladder. 21.—Laurel Leaves. *Oreodaphne Californica.* Aromatic, carminative, sedative, and antiseptic. 22.—Laurel Tree Bark. *O. Californica.* Possesses the properties of the leaves in a reduced degree. 23.—Life Everlasting. *Gnaphalium macrocephalium.* Anodyne, diuretic, suderific, and narcotic. 24.—Lilac Tree Bark. *Ceanothus thyrsiflorus.* Demulcent, tonic and antiperiodic. 25.—Loco Weed. *Oxytropis campestris.* Poisonous. Powerfully narcotic and repressant. 26.—Madrona Leaves, *Arbutus Menziesii.* Tonic and astringent, with a stimulant effect on the urinary organs. 27.—Madrona Bark. Possesses properties similar to the leaves, in a reduced degree. 28.—Manzanita Leaves. *Arctostaphylos glauca.* Astringent, tonic and diuretic. 29.—Maple Bark. *Acer macrophyllum.* Tonic, astringent and ophthalmic. 30.—Mistletoe. *Phoradendron flavescens.* Nervine, antispasmodic, narcotic, and emmenagogue. 31.—Oak Bark. *Quercus densifolia.* Tonic and powerfully astringent. 32.—Oak Excrescences. *Quercus lobata.* Contain a notable percentage of tannin. 33.—*Rhamnus tomentilla,* Bark of. Similar in properties to Cascara Sagrada, but in a reduced degree. 34.—Romero. *Trichostema lanata.* Anthelmintic. 35.—Sage, Wild. *Artemesia Californica.* Bitter tonic, aromatic, and discutient. 36.—Sneezeweed, or Swamp Grass. *Helenium puberolum.* Errhine, tonic, alterative, and antisyphilitic. 37.—Spikenard Root. *Aralia Californica.* Diaphoretic, diuretic, and expectorant. 38.—Tar Weed, Blue. *Trichostema lanceolata.* Balsamic, strongly terebinthinate, diuretic, and counter irritant. 39.—Tar Weed, Yellow. *Hemizonia corymbosa.* Highly odorous, tonic, cathartic, and discutient. 40.—Tyene Bark. *Heperomale arbutifolia.* Tonic, astringent, and sedative. 41.—Tyone Leaves. Carminative, antispasmodic, and sedative. 42.—Willow Bark. *Salix longifolia.* Astringent, tonic, antifebrile, and aromatic. 43.—Wild Sunflower, or Turpentine Root. *Wyethia helenoides.* Stimulant to the secretions, expectorant, and diurectic; tonic to the kidneys and bladder. 44.—Wormwood. *Artemesia absinthium.* Properties similar to the Eastern grown plant, in an enhanced degree. 45.—Yarrow. *Achillea millefolium.* Tonic and emmenagogue. 46.—Yerba Buena. *Micromeria Douglassii.* Anthelmintic, carminative, and antiperiodic. 47.—Yerba Marra, or Man Root. *Megarrhiza Californica.* Drastic cathartic, hepatic, and antiperiodic. 48.—Yerba Reuma. *Frankinea grandifolia.* Given with success in catarrh, gonorrhœa, leucorrhœa, and catarrhal rheumatism 49.—Yerba Santa. *Eriodyction glutinosum.* Tonic, expectorant, and diuretic. Useful in diseases of the throat, lungs, &c. 50.—Leaves of the *Rhamnus Purschiana* and *Berberis aquifolium,* mounted and framed.—*Oil and Drug News.*

CULTIVATION AND PRODUCTION OF PINE-APPLES IN THE BAHAMAS.

The cultivation and shipment of pine-apples is, according to Consul McLain, the most important industry of the Bahamas, much capital, and very many people being employed in it, so that the material prosperity of the colony, from year to year, depends largely upon the success or failure of the crop. Of the several varieties of pine-apple, only two are considered profitable to cultivate for exportation, the 'scarlet" or Cuban pine, and the "sugar-loaf." The former was introduced to the Bahamas from Cuba in 1850, and is now the leading variety of commerce; the latter, a very luscious fruit, is exported principally to England. The Bahamas generally are noted for the thinness of the soil, which seldom exceeds a depth of from six to eight inches. The islands are composed largely of a species of limestone, made up of sand, carbonate of lime, and the remains of myriads of defunct coral insects, so that the rock itself is a very good fertiliser; in fact

prolific vegetation flourishes apparently upon the bare rock, the surface of which is broken and honeycombed, the small openings being full of vegetable mould, and furnishing holding-places for the roots of not only plants and grasses, but often of large and stately trees. The ordinary soil of the Bahamas is not fitted for the cultivation of the pine-apple, as this plant requires a depth of at least two feet to be grown successfully. But upon many of the islands, extensive tracts of soil are found, composed of a reddish clay, about two feet deep, and these are peculiarly adapted to the pine-apple; this soil is very rich, being, as geologists say, composed of the decayed remains of decomposed vegetable life, and the *debris* of shell-fish and coral insects, each cubic foot of the soil representing the decay of about 1,000 times that quantity of original matter. In preparing a field for planting, the dense natural growth of bush, or *chaparral*, is first cleared away, and this is done by cutting and burning, the cutting being effected by the blacks, with heavy, long-bladed knives called "machetes." The plants are then set out about two feet apart, when they take root, and grow very quickly, great care being taken to keep down the weeds. The fruit comes to maturity in from eight to nine months, at which time the main stalk dies, leaving an abundance of young sprouts, which in turn spring up and bear fruit. The bush or plant upon which the pine-apple grows, is at maturity about thirty inches high, having long, slender, hard, blade-shaped leaves, with serrated edges. The leaves bend outward from the centre, and out of this centre the fruit springs, one pine-apple only to each plant. An acre of good land will easily support 6,000 plants of the sugar-loaf variety, or about 5,000 of the scarlet kind, and there is a large quantity of land in the Bahamas eminently adapted for the purposes of growing pine-apples which has never yet been cultivated. The price of good land varies between £1 and £4 per acre, and depends upon the size, the fertility of the soil, and its proximity to a suitable place for shipping the fruit; and as much of the fruit is taken on board vessels which call along the coast during the season, a plantation which borders upon some cove, bay, or good anchorage, is a valuable one. The average life of the scarlet pine is three years, and that of the sugar-loaf about five. The average weight of the fruit in the Bahamas is from three to three and a half pounds. A field is generally gone over three times during the season, affording three grades of fruit, called first, second, and third cuttings. The scarlet variety ripens a month or two earlier than the sugar-loaf. Owing to the sharp serrated leaves of the plant, the gathering of the fruit is a tedious and difficult matter, the men, women, and children engaged in the work being obliged to wear heavy canvas leggings and gloves with gauntlets to protect themselves against the sharp spikes of the plant. The pine-apple plants furnish but one regular crop during the year, although the local markets are seldom without pine-apples for sale. The first cuttings of the scarlet pines are made about the middle of April, and the last is made about the 1st of July. The sugar-loaf pine is at maturity during July and August. The shipping season is one of great activity in the Bahamas, as when the fruit is ready for the knife, it must be cut and hurried with all speed to market, or it will be lost. It is estimated that from seventy-five to one hundred cargoes of fruit are shipped from April 15th to July 15th, and about 40,000 pine-apples make an average cargo, the total exports reaching from 4,000,000 to 5,000,000 pine-apples during the season. The fruit for shipment is never allowed to ripen, but is cut when green, as soon as it is full of juice, otherwise it would spoil before reaching a market. The average price paid for the fruit is about 1s. 9d. per dozen for first cuttings, 1s. 6d. for seconds, and 1s. 3d. for thirds. Some growers export their own fruit, others sell to local buyers who purchase the crop at the foregoing figures. The pine-apple business, though a lucrative one, is very hazardous; if everything is favourable good profits are realized, but a few untoward circumstances will bring ruin. Occasionally there is too much rain or there is drought; at times armies of rats and land crabs invade and devour whole fields; and, again, bush fires frequently devastate a plantation. As a rule, the scarlet pine-apple is consigned to the United States, the sugar-loaf goes to England. As the latter voyage is a long one, the pine-apple plant is cut off at the root, and plant and fruit are shipped unseparated. The whole of the pine-apple crop is not now exported, a portion being put up or preserved in tin cans, several factories upon the islands being engaged in this work; at one alone, in Nassau, it is estimated that about 25,000 pine-apples per diem are consumed, and 200,000 to 250,000 cans of fruit are put up during the season. The wages paid to the workmen are at the rate of about 2s. a day for men, 1s. for women, and 6d. for children, and even lower wages are paid to plantation hands. For several years prior to 1880 the pine-apple industry was unprofitable to the colonists, owing to a succession of disasters in the way of bad weather, low prices, and decay; but during 1880 and 1881 good crops were made, better prices prevailed, and business materially revived. In 1880, about 340,000 dozen pine-apples were exported; in 1881, about 363,000. There were also shipped about 200,000 tins of preserved pine-apples; in 1880 and in the following year this number was increased to 287,000 tins.—*Journal of the Society of Arts.*

INDIA: CROP AND WEATHER REPORT.

For the Week ending the 10th Oct. 1882.

General Remarks.—Light rain has fallen in all districts of the Madras Presidency except Travancore, where it was heavy. There has also been some rain in Mysore and Coorg, Bengal, Assam, and British Burma. The North-Western Provinces and Oudh, Central India, and the Bombay Presidency report showers in a few districts. The Punjab, Rajputana, the Central Provinces, and the Nizam's Territories have had slight rain in one or two places; there has been none in Berar.

Prospects of standing crops are, on the whole, favourable everywhere, although some more rain would be beneficial in a few places.

Harvest operations continue in many parts of the country. Preparations for, and sowings of, rabi crops are in progress in parts of the Bombay Presidency, Bengal, the North-Western Provinces and Oudh, the Central Provinces, Mysore, the Nizam's Territories, and the Central India and Rajputana States.

In the Bombay Presidency locusts are doing much injury to crops in Khandesh, Ahmednagar, and Nasik.

A general rise in the barometer during the earlier part of the week was followed by a fall of equal extent, less marked in Northern India than in most other parts.

Madras.—General prospects good.

Assam, Sylhet, (Oct. 11th)—Crops reported on favourably from all quarters; cholera and small-pox still reported.

Mysore and Coorg.—Seasonable showers in all districts except Kolar, where more rain is wanted; standing crops generally in good condition; ragi, juari, horse gram, &c., harvested in parts; sowing of other grain continues; public health good; prices easy.

Ceylon Planters' Association.—We have to acknowledge receipt of a copy of the Proceedings of this body for the year ending 17th February, 1882. Apart from a record of the current business of the Association and of political proceedings, there is a large amount of agricultural information, more particularly in respect of new products, coffee leaf fungus, grub, &c. Dr Trimen's Notes on trees yielding India Rubber are also included, and altogether this volume is well worthy of the best of its predecessors.

No Rain for Six Months and Vine Culture in the North-West.—Kalpitiya, 23rd October: We have had a slight drizzle after a spell of six months' drought but still the heat is wellnigh unbearable. The monsoon is now evidently fast approaching and this is a bad sign for the grapes. The grape crop of this place has been fairly good this year as upwards of 20,000 lb. of it had been sold. [Sold to whom? Surely the writer is exaggerating the quantity of crop, or that the crop has been much larger than usual owing to the prolonged drought.—Ed.]

GRANITE IN A TREE.—Upon splitting a white Oak tree cut down in Nevada county, California, there was found embedded in the heart of the trunk, 60 ft. above the roots, a piece of granite weighing about two pounds. A probable explanation is that the stone had been put in the fork of the tree when it was young, and that the tissue had gradually closed upon it after the manner of the Oak tissue around the egg of the gall fly.—*Journal of Forestry.*

STUMPS.—The following receipt has proved very successful in the back-woods of America for removing the stumps of trees. In the autumn, bore a hole of one or two inches in diameter about eighteen inches deep, put in one and a half ounce of saltpetre, fill with water, and plug up close. In the following spring, put in the same hole half a gill of kerosine oil, and then light. The stump will smoulder away without blazing, and the fire will go to every part of the roots, leaving nothing but ashes.—*Indian Agriculturist.*

DIFFERENT KINDS OF TREES attain maturity at different ages, and the same kind of tree will more quickly ripen in one situation than in another. Thus, it is calculated that a teak tree seven years old in Malabar, where the soil and climate are favourable to its growth, will be of the same dimensions as one fifteen years old in Bombay, where the moisture is greatly less. Then, again, the age of a tree is not so easily guessed at as some people appear to think, and the rate of growth as observed in Europe is no criterion of the age of a tree in other countries. The age of the gigantic Eucalyptus trees of Tasmania, put down in a haphazard sort of way at from 200 to 300 years, was proved to range from 50 to 75 years only. The usual calculations of age in this instance were entirely upset by the fact that most of these trees shed their bark twice a year, and the sap moving up the tree twice forms two rings in the wood of the stem, instead of one only in each year of their growth.—*Journal of Forestry.*

THE TREMBLING TREE.—There is a tree, says the *Chicago Lumberman*, which is a species of acacia, that is most peculiar in its habit, and that seems more animal than plant. Some of these trees have been raised in this country as curiosities, and the owners have had strange experiences with them. On one occasion a tree of the kind was grown from a seed brought from Australia, and before very long had come to be a sapling some eight feet in height, when it was in full foliage, and growing rapidly. It is leguminous, and very distinctly shows the characteristics of the mimosa, or sensitive plant. Regularly every evening, when the chickens "go to roost," the tree performs very much the same duty. The leaves fold together, and the ends of the tender twigs coil themselves up like the tail of a well-conditioned pig. After one of the twigs has been stroked or handled, the leaves move uneasily, and are in a sort of mild commotion for a minute or more. While these peculiarities in the tree were understood by these who possessed the one that has been mentioned, it was soon discovered that it had in it much more of life and feeling than it had ever before been credited with. The tree being in a comparatively small pot, which it was fast outgrowing, it was deemed best to give it one of much larger size, but when the tree was removed to its new quarters, it resented the operation to the best of its ability. When it had been fairly transplanted it acted as if furiously enraged, and in a way that suggested that the very demon must be in it. The leaves began to stand up in all directions, like the hair on the tail of an angry cat, or the quills upon the fretful procupine, and soon the whole plant was in a feverish quiver. This could have been endured, but at the same time it gave out an odour most sickening and pungent—just such a smell as is given off by rattlesnakes and many other kinds of venomous serpents, when disturbed. The odour so filled the house, and was so nauseating that it was found necessary to open the doors and windows. It was fully an hour before the plant calmed down and folded its leaves in peace, and it appeared that it had given up the battle only because the hour for its peculiar manner of "retiring" had arrived. It is probably needless to say that the children, and, in fact, the whole household, now stand in abject awe of the strange tree, as being a thing vastly more reptile than vegetable. Many similar experiences, and some even more remarkable, have been had with the different forms of highly sensitive plant life.—*Journal of Forestry.*

MAHOGANY IN SAN DOMINGO.—In consequence of the demand for mahogany of late, it has been feared lest the supplies should fall short; we are assured, however, in a report of the Vice-Consul at Puerto Plata, San Domingo, that the diminution in the exports of mahogany is by no means to be attributed to a scarcity of the wood, for the forests are apparently inexhaustible, but it is to be accounted for through the absence of suitable tonnage for charter in the neighbouring colony of St. Thomas throughout the year.—*Gardeners' Chronicle.*

GINSENG.—The following account of the cultivation of ginseng and the wild plant in Corea is from the report of the Commissioner of Customs, at Newchwang:—The chief item which the Coreans bring across the border is ginseng, and this is the most valuable. Wild ginseng is found amongst the hills, and takes more than 30 years to arrive at perfection. The root can be used when it has been in the ground about 12 years, but it is not so valuable as that of mature age. The other kinds of ginseng, known as first and second quality Corean, are a special branch of culture. Only well-to-do people can afford to set apart the ground for its cultivation, and to devote to it the time which it requires. The usual period allowed for the root to attain its full growth is from five to six years; it is then dug up, washed, and dried in a pan over a fire, and, after the skin has been scraped away, it is ready for the market. Once every year a small red flower is put forth, seed from which is carefully preserved and sown the following year.—*N. C. Herald.*

AN UNWHOLESOME TREE.—Among the enterprises in which a Sanitary Society of Brooklyn is said to be now eugaged is a crusade against the *ailantus trees* which shade many of the streets of that city, as well as of New York. The tree was introduced from China into this country some forty years ago, heralded by extravagant praises, which led to its extensive use for street planting. For a time its hardiness and extremely rapid growth kept it in favour, but the blossoms which cover it for a few weeks in spring have a peculiarly unpleasant odour, and of late years it has gradually been disappearing. Now, however, it is reported that the perfume of the flowers is unwholesome as well as diagreeable, and that "prostration of the nervous system," an "oppressive feeling in the throat," "swollen joints," and other affictions are caused by inhaling it. Under these circumstances it is not surprising that twenty-two "eminent medical men," and over fifty householders, should have signed petitions against the trees; the only wonder is that they should not, as soon as their pernicious character was disclosed, have armed themselves with axes and incontinently extirpated the species from the town. However, the citizens of Brooklyn usually act with a commendable deliberation in such matters, and it is gratifying to learn that the Sanitary Society is "collecting data from physicians and others" before giving the signal for the general destruction of the trees.—*American Architect.*

BANYAN TREES.—A Mexican traveller, says the *North-Western Lumberman*, makes the statement that the much-exagagerated banyan tree, of tropical Mexico, in no way resembles its brother of the Pacific archipelagos, for in the Society Islands he has seen banyan trees whose main trunk measured 30 ft. in girth, while some old patriarchs or giants of their species boasted of over 300 minor trunks or branches, which had dropped to the ground, had taken root, and in turn shot out branches that also fell downward and rooted. The Banyan tree of Guerrero is but a pigmy in comparison. Its main trunk will seldom measure more than from 10 to 12 ft. in girth, and it reaches an altitiude of 30 ft. before it branches, while the limbs may extend 30 to 40 ft. from the parent stem before they incline to the ground and root. It is difficult to find a specimen that possesses more than 20 branch trunks. These trees are quite numerous in the valleys and "barrancas" among the mountains of Guerrero. They are generally found near running water, while, strange to say, their presence in any locality denotes the existence of "placer" gold diggings; at least so affirm the Indians of the vicinity. Yet it is none the less true that all the gold dust that has been gathered in this region was found in close proximity to trees of this species, from which fact it is fair to presume that this theory was originated by the seekers after mineral wealth in that section.—*Journal of Forestry.*

Chinese Forests.—The remark is made by a Texas newspaper that "one of the strongert arguments in favour of preserving forests is to be found in Chinese history. The terrible famine which raged in that country several years ago, wrs brought about by the destruction of the few forests left standing, thereby rendering it impossible for the solie to retain the little rain that fell from time to time."—*Journal of Forestry.*

Verbena.—The well-known fragraut, sweet-scented lemon verbena (*Lippia citriodora*) is regarded among the Spanish people as a fine stomachic and cordial. It is either used in the form of a cold decoction, sweetened, or five or six leaves are put into a teacup, and hot tea poured upon them. The author of a work, "Among the Spanish People," says that the flavour of the tea thus prepared "is simply delicious, and no one who has drunk his pekoe with it will ever again drink it without a sprig of lemon verbena." And he further makes a statement, more important than all the rest, if true, that if this decoction be used one need "never suffer from flatulence, never be made nervous or old-maidish, never have cholera, diarrhœa or loss of appetite.—*Sydney Mail.*

A New Fibre Plant.—The *Queenslander* gives, in its agricultural columns, an account of a new fibre producing plant which is said to be attracting great attention in America just now. It is there known as bear grass, and spanish dagger, and is said to yield largely, requiring no cultivating after its third year, growing for 100 years and producing the strongest coarse fibre in the world. Such ample recommendations as these are likely to cause people to pay more than ordinary attention to this plant, and we can only hope that it may turn out to be as good as it is reported to be. The experience of Queensland with fibre producing plants has not, we regret to say, been a very fortunate one. Mr. MacPherson of Brisbane has proved himself an adept in the preparation of beautiful show cases of fibres grown in this colony, but as yet we have heard of no financially successful opcrations in the way of fibre growing. When sida retusa was first introduced to us, its advent was heralded by a description of its economic value very similar to that given of bear grass, but practically it has been found that sida is one of the greatest curses of Queensland agriculture. In order that our experiences in this direction may not be repeated with bear grass, we would suggest that the Government should have an acre or so of it grown in Brisbane as an experiment. If it proves equal to what is asserted of it, there would be no difficulty then in adding bear grass fibre to the list of our products; if on the other hand it proves a second sida, we should like to have it made criminal for any one to grow it.—*Australasian.*

The Quillaia Tree.—Attention has recently been drawn to the commercial value of the quillaia tree (*Quillaia saponaria*), a native of Chile, the bark of which has been known for a considerable time both in this country and on the Continent, for the saponaceous principle which it contains. In consequence of the trees having been cut down to obtain the bark, there is much reason to fear that the supply may fail, particularly if the demand increases. Quillaia bark it seems, is very extensively used by wool and silk manufacturers both in this country and in France, in consequence of its efficacy as a powerful cleansing agent. Our contemporary, the *Colonies and India*, in drawing attention to this tree, remarks, "that a decoction prepared by placing a small piece of this bark and soaking it over night in water will remove in a minute or two grease from articles of clothing and leave the cloth clean and fresh as if it was new. It may also be used for cleansing hair-brushes and other similar purposes, under conditions in which soap and other alkalies are powerless. It is also suitable for a hairwash, and is said to be largely used by French hairdressers, though the mode of preparation is kept secret. Such a tree ought to be invaluable in Australia, New Zealand, Cape Colony, and other colonies where wool growing is a staple industry." Among the uses to which this bark is put may be mentioned that of a preparation for giving an artificial froth or head to ales, a very small quantity put into beer that has become dead causing it to be covered with froth. The bark occurs in commerce in two forms, that of irregular pieces as taken from the tree, and in the form of powder.—*Nature.*

Packing Peaches for Distant Markets.—Pick peaches carefully. Let them be well coloured, but firm, not soft. Wrap each peach in stiff brown paper, not in tissue paper. The former is more elastic, and prevents bruising. In packing lay them in with the greatest care. Fill the box full so that the peaches cannot shake about. Put a layer of clean fine oat straw at the bottom of the box, and paper between the other layers and over the top one. —*Californian Horticulturist.*

Preparation of Coffee.—Mr. Clement Wragge, F.R.C.S., in a recent number of the *English Mechanic*, gives the following recipe for the preparation of coffee in the Arabian fashion. Roast some raw nibs, and pound them down; when your water is boiling put in the coffee so treated, and stir it about. Next place the pot again on the fire, and carefully manipulate it, if occasion requires, till simmering sets in, when you must immediately remove it, and pour the contents into the cup. Milk or cream should never be added, but a little soft brown sugar may be used to suit the taste; also a little cardamom seed. Smoking a pipe of Turkish tobacco is only needed to give additional flavouring to your sips, and to transport you temporarily to the delights of the Muslim's paradise.

The Lac industry is one peculiarly adapted to the natives of this country. It is one which requires no forethought or preparation. The villager has nothing to do so far as that work is concerned, but remain at home till the crop is ready for gathering. Nature does all but collect the harvest. Such is the manner of conducting this industry common to the mofussil villager. If he had a spark of energy or enterprise, he would assist nature, and thereby materially increase his own income. The way to assist nature is to take small twigs bearing insect cells, and fasten them to trees hitherto unvisited by the insects. All he would require to do would be to break off a small twig, and carry it to a tree or bush in the neighbourhood, fastening it to a branch with a little grass or straw to prevent its being blown off, until the young spawn had had time to attach themselves to their new habitation. A few hours' work of this kind would very materially increase his harvest. It appears that the cultivation of the lac insect has taken root in the Punjab, especially in the district of Hoshiarpore. The Punjabee with his characteristic energy is fast inoculating—if we may use the term—the forest in the neighbourhood of his village with the spawn of the lac insect; and one great advantage connected with this work is, that the return is pretty sure and is certain to be speedy. The industry might be pursued all along the Sewalik range, where the height does not reach a frosty climate. The trees most frequented by the *lac* insect are the peepul (*Ficus religiosa*), the bêr (*Zizyphus jujuba,*) the banyan (*Ficus indica*), and various other trees common to those districts. The lac produced on the bêr is the best, and this is a fortunate circumstance, as the tree is as common in Upper India as a hedgerow at home. Before the mode of producing this *lac* was understood, a prejudice existed against it, as it was not known to be of animal origin, but was supposed to be the result of a disease of the tree, and therefore unclean. It is astonishing, however, how these prejudices vanish in the face of a profitable industry. The only difficulty at present found in the Punjab, is the greed of the collectors, who would leave nothing but stumps, thus to a certain extent slaying the goose that lays the golden eggs. The bêr has been found to possess considerable vitality, and does not resent very heavy prunings, but supplies the place of lopped twigs with unfailing certainty the following season. The mode of preparation is simple, and the appliances of no great cost. It is crushed in the *denki*; the particles of wood disappear on the powder being thrown into water, the wood immediately floats, and is removed at once. The powder is then thoroughly washed, and the lighter particles laid aside for making lac for bangles, &c.; the heavier particles, lying at the bottom of the tubs, are pressed into cakes to make the lac-dye of commerce. The light powder is put in a cotton bag which is rolled tight, and held in front or over a hot fire; the lac melting exudes through the bag, and is carefully collected and spread over hot surfaces, to form cakes, known as hell-lac. The industries might all be made by-work for the farmer, as their prosecution need not interfere with his more important occupation.—*Friend of India.*

CHINESE VARNISH TREE.—In Dr. Bretschneider's notes on some botanical questions connected with the export trade of China, it is remarked that "It is generally accepted by authors writing on Chinese varnish, that it is produced by *Rhus vernicifera*, the Japanese varnish tree." The Chinese varnish tree is found in the provinces of Chè Kiang, Kiangsi and Sze-Chuen. According to Bretschneider the figures of the tree in Chinese botanical books do not at all resemble *Rhus vernicifera*. I learn from Mr. H. T. Murton that a Chinaman at Singapore has about forty acres planted with varnish trees. Specimens sent to Kew prove that it is *Aleurites vernicia*(=*A. cordata Elæococca vernicia*). Seeds of this plant had been previously obtained through a correspondent from Sze-chuen, and have been distributed to Ceylon, Demerara, Dominica, Jamaica, Washington (Department of Agriculture), and Zanzibar. Dr. Kirk reports (September 9) from the last-mentioned place that the seedlings "are all a foot high, and I am planting them out."—*Journal of Applied Science.*

SUCCESSFUL MELON-GROWING.—Mr. C. Smith describes in the *Gardener* as follows a fine crop of melons at Cardiff Castle:—"The plants, seven in number, were planted in a border 2ft. wide and 14in. deep, in a compost of soil which had produced two crops of melons before the crop I am going to describe. Mr. Pettigrew is not particular as to the quality of the soil he uses for growing melons. His success depends more on giving the plants liberal supplies of liquid manure and light top-dressings, to induce root-action near the surface, than trusting to any special soil. Three crops were taken from the plants which I allude to—namely, eight fruit from each plant each crop, or 24 melons from each plant, making a total of 168 fruit to the seven plants, which averaged 3½lb. each, or, in all 588lb. Many of the fruit of the first crop were more than 5lb. or 6lb. each, but they were smaller in size towards the end of the season. They were, however, all presentable fruit, and none of them under 2lb. in weight, and of the very best quality. The variety which produced the enormous crop was Eastnor Castle, green-fleshed kind."—*Australasian.*

NOTE ON HEDYOSMUM NUTANS AND CRITONEA DALEA.—Some months since a sample of a fragrant volatile oil, said to come from Jamaica under the name of tobacco bush oil, was presented to the Museum by Mr. J. C. Sawer. As that name was not to be found in Lunan's "Hortus Jamaicensis," nor in Barham's "Hortus Americanus," I wrote to Mr. D. Morris, the Director of the Botanical Department at Gordon Town, Jamaica, who has informed me that "the name (of tobacco bush) is applied to *Hedyosmum nutans*, Sw., a common plant on the Jamaica hills, as about Port Royal and on the Blue Mountains, at an elevation of 5,000 to 6,000 feet above the sea. It is also called headache weed, and is generally used by the natives for making tea and for binding around their heads when in pain." Rosenthal states that the leaves and flowers are used as a stomachic and antispasmodic. The plant is now placed in the Chloranthaceæ, although the genus was referred to the Amentaceæ by Sprengel, and to the Caprifoliaceæ by Reicheubach. The flowers are unisexual, the males bractless, in small, close, oblong spikes; the females sessile on a corymbose inflorescence. The leaves are opposite, lanceolate acuminate and serrate, with the bases of the petioles united so as to form a short sheath around the stem. The flavor of the leaves is pungent and aromatic, and the odor like that of scented soap. Indeed, if the oil could be obtained at a cheaper rate it would make a very agreeable perfume for soap, and if it really possesses the property of relieving headache, might form a useful addition to smelling-salts. Another plant which is known in Jamaica by the similar name of cigar bush, or cigar maker's vanilla, is the *Eupatorium Dalea* (*Critonea Dalea*, D. C.). This plant grows to a height of 6 to 10 feet; has lanceolate, tapering, thin, smooth, somewhat shining, distantly serrulate, opposite leaves, 4 or 5 inches long, and ½ to 1 inch broad in the widest part. When held up to the light they are seen to be marked with pellucid lines and points, something like those of the balsam of peru tree. The leaves are very fragrant, the odor, which is very persistent, resembling that of new-mown hay or tonka bean. The leaves might well form a cheap substitute for tonka bean in perfumery, while a tincture might be useful for disguising the odor of iodoform.—*Pharmaceutical Journal.*

CARBOLIC ACID IN SMALL-POX.—Dr. C. W. Thorp writes to the *British Med. Journal*:—"I have found the carbolic-acid glycerine of the British Pharmacopœia, diluted with four times its weight of glycerine, a most useful application in small-pox. It should be applied as soon as the pustules begin to fill, and be continued until they desquamate. Such treatment, I think, not alone renders the patient less repulsive to those about him or her, but lessens to a great extent the pitting resulting from the disease."

DESTROYING AMERICAN BLIGHT AND MILDEW.—An English contemporary thus answers an inquiry:—If you dissolve 6oz. of soft soap in a gallon of water, adding a wineglassful of paraffin, and apply the mixture to the trees with a brush, rubbing well into the crevices of the bark, it will destroy the insects. Any portions of the trees that are seriously affected may be dressed with pure paraffin, but it must not be applied to the buds nor to the smooth bark, nor so freely as to drain from the trees into the soil. The soft soap and paraffin must be thoroughly mixed together, and the remedy will be safe and effectual. After your roses are pruned dress them with a mixture of lime and sulphur with a little clay added to make the "paint" adhere to the stems. In the summer syringe them frequently with a solution of soft soap, and it will to a very great extent prevent the mildew appearing.—*Australasian.*

SAWDUST FOR PROPAGATING PLANTS.—I have never found any material that produces roots so quickly, surely, and numerously, in all plants that I have tried in it as sawdust fresh from the forester's sawmills, and it does its work perfectly for 12 months without being renewed. Pitcher-plants, including such varieties as lanata and sanguinea, strike freely in sawdust, and scarcely a cutting of any plant fails in it. I never saw plants make such enormous numbers of rootlets in any other material. I once potted a pine-apple in it, and in a very short time the whole dust was so permeated with roots that when they were washed clean they resembled a wig of roots more than anything else. A camellia was tried in it with the same result. These facts may be of service to many who are able easily to obtain sawdust who cannot so easily procure silver sand or cocoa-nut fibre refuse. The sawdust used here is from spruce, larch, and oak, all mixed together and laid about 4in. thick over a heated chamber.—D. THOMSON, Drumlanrig, in *Journal of Horticulture.*

THE VINE PEST.—The battle with the phylloxera is still kept up here and there in France, but in a disheartened way, and all too late. There is no doubt whatever that where submersion can be employed, and a foot or so of water can be kept on a vineyard for six weeks in the year, the phylloxera can be drowned out. But the treatment costs too much, except in naturally favourable situations, and it weakens the wine. The area thus treated is quite insignificant—not more than 12,000 acres annually for the last three years. The application of chemicals also continues, but not to so large an extent. Bisulphate of carbon is the only matter yet discovered which, carefully applied, kills the phylloxera without hurting the vine. It is at best only a partial remedy; for its application to the roots three or four times a year requires many skilled labourers, and is so costly as to be confined to vineyards which give a large margin of profit—such as those which yield "grands crus." While M. Balbiani hunts after the "winter egg." M. Dumas, taking a hint from Pasteur's discovery about the corpuscles of the silk-worm disease, is searching for a contagious malady or parasite with which he can inoculate the phylloxera, for he maintains it must have a natural enemy of the kind. The reward of £12,000 for the invention of a method of destruction still remains open, and the oddest proposals are year by year renewed. Vinegar and sea-water are very much in favour with these dreamers; even coffee-grounds and church incense have been suggested. Some strongly urge the employment of small birds and even ants; while others sagely propose to graft the vine on mulberry-trees, wild briars or gooseberry bushes. But the lonely rays that light up the dark prospect are the hopes founded on the essays made with the American vines.—*St. James's Gazette.*

A PREHENSILE TREE.—Darwin tells of flowers which seize upon flies and small pieces of raw meat-which having secured with a gauze-like net-work they proceed to eat. Lieutenant Houghton, who recently visited New Guinea and the islands in the Pacific, tells of a tree which has the power of picking up articles from the ground. It is a species of Ficus, closely allied tothe banyan; and, like it, throws out from its branches long flexible tendrils, which twine themselves round any article within their reach. By-and-by the branches conract, but still firmly grip the object round which they have twined themselves, and suspend them in mid are.—A. B. in *Land and Water.*

ON A CHARACTER OF THE SWEET POTATO.—In the *Archives des Sciences Physiques et Naturelles* M. Alph. de Candolle calls attention to the nature of the roots of the Sweet Potato, Batatas edulis. He says, what has not been sufficiently noticed is that root-tubercles are exceptional in the Convolvulaceæ, and that the Sweet Potato is perhaps the only member of the family having them. Unlike the enlarged underground part of the Potato or of the Jerusalem Artichoke, the enlarged part of the Sweet Potato is strictly a root formation, that is, it has no buds or eyes. Potato tubers are underground resting-stems or branches, which in due season produce aërial stems, roots, and tubers. M. de Candolle regards the stocks of Jalap, Scammony, and other members of the Convolvulaceæ as stem-formations. —*Gardeners' Chronicle.*

COFFEE AND TEA IN RUSSIA.—Most of your readers are doubtless aware that the bulk of your Ceylon peaberry exported from this country goes to Russia, and that in fact the Russians take very little Ceylon coffee besides, but it may be news to some of them that this Ceylon peaberry is invariably sold in Russia under the name of Mocha. An old Ceylon resident was telling me yesterday that when recently at Moscow he pointed out in a warehouse there two barrels of peaberry with the mark of his own firm's mill upon them, but his cicerone, a Russian merchant, insisted nevertheless that it was Mecha coffee! He had always sold it as such and that was proof positive to him. It is, I suppose, only the old idea, once prevalent here, cropping up in an out-of-the-way place, that all coffee must needs come from the green hills of Yemen, because it is the Arabian variety, for there is certainly no sort of resemblance in Ceylon peaberry to the genuine Mocha. My informant was rather surprised to find that coffee was so little drunk in Russia. Tea is consumed everywhere and by all classes, but coffee only in the large towns and not much there.—*Cor. C. Times.*

THE FEVER TREE.—The *Eucalyptus globulus*, which is being introduced in California, has many qualities which recommend it to Eastern sylviculturists. It comes originally from Australia, where the tests of various soils and varying seasons have amply demonstrated the good qualities of the tree, and its rapid growth even under adverse surroundings. Trials of late years in Southern Europe have further verified these claims, and there is no reason why the tree will not flourish in every section of the United States. It is hardier than the chesnut, and, like the latter, it will grow in the rockiest soils. It is more independent of rain food than any tree known in this country, wet and dry seasons alike failing to affect its growth. Its wood is hard, somewhat of the nature of yellow pine, but firmer and stronger, and fit for use in ship timbers, while in Australia cabinet-makers, wheelwrights, and carpenters use it throughout their trades. The bark yields a febrifuge second only in efficiency to quinine, but, superior in all medical qualities to cinchona.* This quality alone must make the tree invaluable, and its culture here, to an appreciable extent, would settle for ever the vexed question of quinine duties. The rapidity of its growth is its most wonderful feature. It grows four times as fast as the American pine, and for all ordinary purposes is fit to cut in five or six years. For the Eastern and Middle States, where the lack of forest protection is not infrequently felt, no tree has been offered the culturist that can present so many primary points of vantage as the Australasian immigrant, and its general introduction and culture should only be a matter of but little time. It may be added, the tree yields fragrance, but produces no fruit or nut. Its beauty of form and luxuriant evergreen foliage are additional qualities that must recommend it in country or city.—*Frank Leslie's Illustrated.*

* ? Cinchonidine.—ED.

AGE OF TREES.—A scientist interested in the study of cosmography, says the *North-Western Lumberman*, adduces the point that the great trees of California, with from 1,350 to 2,550 annual rings of vegetable growth, reveal the fact that these monarchs of the vegetable world were saplings when Nebuchadnezzar was born. Forests have likewise been estimated to have been 4,000 years old, and to have grown from seed propagated by elder parent trees, and these, in turn, from grand-parents, whose crumbled dust forms a rich vegetable mould to nourish their younger progeny. How many such generations occurred no one can tell.—*Journal of Forestry.*

INFLUENCE OF COAL ON FLOWERS.—A correspondent of the *Revue Horticole* states that he bought a very fine rosebush, full of buds, and, after anxiously awaiting their maturing, was greatly disappointed to find the flowers small, and of a dull, faded color. At the suggestion of a friend he then tried the experiment of filling in the top of the pot, around the bush, to the depth of half an inch, with finely pulverised hard coal. In a few days he was astonished at seeing the roses assume a hue as brillant and lively as he could desire. He tried the same experiment upon a pot of petunias, and soon all the pale-colored ones became of a bright red or lilac, and the white ones were variegated with beautiful red stripes. Some of the lilac petunias became a fine dark blue. Other flowers experienced similar alterations; those of a yellow color alone remained insensible to the influence of the coal.—*Queenslander.*

HOW PLANTS FEED.—It is now recognised that a plant does not draw its food from a nutritive solution fully prepared, but prepares it itself by direct and intimate contact of its cells (which have always a slightly acid reaction) with the earth particles, in which nutritive elements have been fixed by way of physical absorption or chemical precipitation. The analytical chemist has to use strong mineral acids to redissolve these fixed matters, and there is the inconvenience that the acids also dissolve elements in combination by which a plant could not directly benefit. Hence imperfect information as to the degree of fertility of soils. M. Petermann is now seeking to develop a new method of analysis—viz. by dialysis of arable soil. In a preliminary paper to the Belgian Academy he finds that (1) arable soil yields to distilled water, from which it is separated by a vegetal membrane, the following nutritive substances: lime, magnesia, oxide of iron, potash, soda, chlorine, sulphuric acid, silicic acid, phosphoric acid, and nitric acid. (2) Arable soil contains organic matters which pass easily by diffusion through a vegetal membrane.—*Public Opinion.*

A NOVEL and interesting experiment for felling trees by electricity instead of with the axe, was recently attempted in the compound of the Strangers' Home, Bombay. The patentees of the process are Mr. H. S. Parkinson and Mr. W. H. Martin, both of Bombay, and the experiment was superintended by Dr. Lyons. The plain is simple. The two ends of the copper wires of a galvanic battery are connected with *platinum* wire, which, of course, instantly becomes red hot, and while in that state, it is gently *see-sawed* across the trunk of the tree to be felled. When arrangements were made for the experiment, it was never for a moment doubted that the enterprising merchants of Bombay were possessed of all the made thicknesses of *platinum* wire, but it turned out that the thickness of the thickest that could be got, was only that of crochet cotton. It was at once seen that a wire of such thickness would be consumed before the tree was half severed from its trunk. However, the attempt was made. The burning wire performed its task very well so long as it lasted, but as anticipated, the wire continually broke, and at length there was no wire left. There can be little doubt that with a stronger battery—the one used was only a twelve-chambered one—and a thicker wire, the experiment would have been entirely successful. As it was, the tree was sawn one-fifth through. It is calculated that under proper conditions, a tree, which at present takes two hours to fell, will come to the ground by this process, in fifteen minutes. It is almost needless to add that there is no waste of wood, no sawdust. The process is one worth the attention of all Governments engaged in forests clearing; and we hope to hear of its being tried on a large scale. —*Indian Agriculturist.*

MARKET RATES FOR OLD AND NEW PRODUCTS.

(London Price List, September 28th, 1882.)

IMPORTED FROM MALABAR COAST, COCHIN, CEYLON, MADRAS, &c.	QUALITY.	QUOTATIONS.
BEES' WAX, White	Slightly softisb to good hard bright	£6 10s a £8
Yellow	Do. drossy & dark ditto	£5 a £6

THE CINNAMOMUM "CASSIA" OF CHINA, SOURCE OF THE "CASSIA LIGNEA" OF COMMERCE.

It may be known to some of our readers that, owing mainly to the silence of the ancient chronicles, the question has been hotly debated amongst scientists, especially in Germany, as to whether cinnamon was indigenous to Ceylon. As one of the oriental names of sugar is simply a modification of the word China, so cinnamon has been traced to a similar origin. *If* our cinnamon came to us from China, far back in the ages, then soil, climate and cultivation have effected a very great improvement. The tree, however, is scattered over our forests, up to near the summit of our highest mountain, which is 8,295 feet above sea level, and we believe that botanists are now agreed that the precious spice tree is really indigenous to Ceylon It is curious that a somewhat similar controversy should have raged over the origin of the cassia bark of China. There was not, we believe, any question that the bark came from China, but only as to whether it owed its origin to one tree, a species or variety of cinnamon, or was gathered from several trees of different species. Sir Joseph D. Hooker, anxious to have the question set at rest, moved the Earl of Kimberley in the matter, and at his lordship's instance, Mr. Charles Ford, Superintendent of the Botanical and Afforestation Department, Hong Kong, was deputed to visit the districts, up the West River, (Sai Kong), in which cassia is produced. The main scene of the cassia culture is so close to Hong Hong, which is situated in N. Lat. 22·12 and E. Long. 114·15, (16° further north and 34° further east than our cinnamon districts), that the meteorological conditions cannot be very different. The mean monthly temperature of Hong Kong ranges from 55°–63° in January to 85° in July and August, the annual means being from 73°–74°. The annual rainfall ranges from 66·66 inches to 111·57, so that the average is much what ours in Colombo is. The chief climatal differences are the much lower degree of cold experienced and the fall of the vast bulk of the rain in South West monsoon months—May to September. October gets a fair quantity, but a dry season extends from November to April, although in some years a good deal of rain falls in March and April. The 16° further from the equator, probably influences the quality of the China bark as compared with our Ceylon spice, but the main differences must arise from the widely opposite conditions of soil, situation, culture and harvesting. Our regularly cultivated cinnamon is all grown on flat plains, and much of it in the fine sand we noticed in our previous article. The whole of the China cassia trees are, it appears, grown on the sides of hills which rise to an altitude of 1,000 feet, the plantations being terraced. The bark also is taken from plants six years old, instead of from stems of about three years' growth as with us, and the epidermis is actually removed by a plane instead of being scraped away by the knife of the cinnamon peeler. Our readers will peruse with interest the following account which Mr. Ford gives of the culture of China cassia —

"Plantations exist on situations with all aspects, any particular one not, apparently, receiving consideration in preference to others. They are at altitudes of from about 300 to 1,000 feet above sea level, and on slopes of from about 50 to 30 degrees Plantations were nowhere seen on level ground, in fact so very little level ground exists in the localities of cassia cultivation that, even if wanted, it could not be obtained. The very small portions of level ground that there are in the bottoms of small valleys, are used for the cultivation of rice and vegetables. Land carrying the thickest vegetation of grass and ferns—*Gleichenia dichotoma* chiefly—is selected. Naturally the soil contains a fair quantity of humus for a depth of from six inches to a foot, but the accumulation of vegetable matter is not more than to give the soil a light brown colour; the consistency of the soil is from friableness to hardish compactness. If very dense the vegetation is burnt. The soil is dug to a depth of about one foot and placed in small terraces or steps three feet apart, and of a width varying according to the steepness of the hills, frequently they are not more, sometimes even less, than eighteen inches wide. No manure is used either when the ground is prepared or subsequently."

The plants are placed in the ground at distances of three feet apart. The peeling of the bark and the gathering of the buds and leaves (for all are utilized by the Chinese) are thus described :—

"*Bark.*—When the trees are about six years old, the first crop of bark is obtained. The season for barking commences in March and continues until the end of May, after which the natives say the bark looses its aroma and is therefore not removed from the trees. The branches, which are about an inch thick, being cut to within a few inches of the ground are carried to houses or sheds in the vicinity of the plantations. All the small twigs and leaves being cleared off, a large bladed knife, with the cutting edge something like the end of a budding knife, is used to make two longitudinal slits, and three or four incisions, at sixteen inches apart, round the circumference through the bark; the bark is then loosened by passing underneath it a kind of slightly curved horn knife with the two edges slightly sharpened. Pieces of bark sixteen inches long and half the circumference are thus obtained.

"The bark, after its removal and while it is still moist with sap, is then laid with the concave side downwards and a small plane passed over it and the epidermis removed. After this operation the bark is left to dry for about twenty-four hours and then tied up in bundles about eighteen inches in diameter and sent in to the merchants' houses in the market towns.

"*Leaves.*—The leaves, which are cleared from the branches that are barked, are carefully preserved and dried, and afford by distillation cassia oil. A large quantity of leaves are sent to Canton, where, I was told, the operation of distilling is performed.

"*Twigs.*—These are removed from the cut branches at the same time as when the leaves are obtained. They are a marketable commodity for native uses.

"*Buds.*—Cassia buds are the immature fruits. They are gathered when about one eighth grown. Buds, and the seeds which are annually required for sowing are obtained from trees ten years and upwards of age that are left standing at about fifty and a hundred feet apart amongst the trees which are cut down every six years for their bark. These seed-bearing trees are not cut, unless there is a demand for the very thick bark on their trunks, when some of the trees which can be conveniently spared are sacrificed."

The small twigs being utilized, nothing is said about distilling oil from the bark, but the leaves seem in great request for the distillation of "cassia oil." The leaves of our Ceylon plant, which are excessively brittle, give out, when broken, the odour, not of cinnamon but of cloves, and all we have ever learnt about leaf oil and its uses in Ceylon is that, rubbed inside the boards of books it preserves the books from fungi and insects. Are we right in assuming that our cinnamon growers leave all small twigs and leaves on

the ground, when cutting the matured sticks? We have never heard of cinnamon leaf oil as an article of inland sale or external commerce, and, as we noticed on Wednesday, the idea of utilizing the immature seeds as cinnamon buds seems never to have occurred to any one in Ceylon. Why? And could not a market be found for the very powerful essential oil so plentiful in the leaves of the cinnamon laurel? If the information which Mr. Ford obtained regarding the yield per acre and money returns of the China cassia culture are correct, we can only feel astonishment that much of the culture is not abandoned, instead of being persevered with and even extended. Mr. Ford gives the figures thus:—

"The yield per acre is probably about 11 piculs which is sold by producers for about $1.70 per picul, *i. e.*, $18.70 per acre, which, as the bark is only obtained once in six years, gives but $3.11 per annum per acre for the bark, but in addition to this a little must be added for the income from the sale of leaves and "buds;" the former, however, would be very small as they only realize about 20 cents per picul when dry, the latter fetch $15 per picul and are a yearly income; but no satisfactory information could be obtained as to the production per acre"

A gross money return of under R40 per acre per annum is poor enough, in all conscience, without following Mr. Ford into what we cannot but consider an error, from his want of knowledge of the system adopted in cinnamon culture. With us there are many, perhaps a dozen plants in the same stool, the stems of which are cut annually, in succession, as they attain the age of about three years. It is possible, although Mr. Ford did not notice it, that the same system is adopted by the Chinese cassia cultivators, but, even if there is only one plant in each hole, it is not credible that all the trees would be cut down simultaneously, and that then there would be a blank in harvesting for six years! Mr. Ford describes a system of coppicing, which must, as in Ceylon, result in stems which will ripen at varying periods and so be ready for cutting, year by year. Instead, therefore, of the starvation return of $3·11 per acre per annum (a little over R6!), the gross return from bark, twigs and buds must be somewhat over R40 per acre per annum, of which probably R20 net remain to the grower.

Mr. Ford remarks:—

"It has been thought that the 'yield is gradually decreasing' in consequence of the 'prices of late years shewing no profit to producers.' From the following table of the quantities and values of cassia exported from Canton the above assertion is scarcely borne out, as although the yield in 1881 was much less than in 1879, yet it compares favourably with the past ten years, being higher than in 1871–73–74–75–76–77, and 80. and not much less than in 1872; 1879 seems to have been the best year on record, over 100,000 piculs having been exported. Although the yield does not thus seem to be decreasing yet the prices have fallen very much; in 1875 they fell to less than one half what they had been for the previous 13 years, and they have not since recovered, but seem rather to be a little decreasing. In spite of these bad times the producers continue to make large annual new plantations, which would seem to indicate that there is still some profit to be made."

If the figures which Mr. Ford has borrowed from Simmonds' book can be depended on, then the increase in the export of cassia from China in twenty years has been enormous and quite accounts for the depression in the Ceylon cinnamon trade. The rise has been from 7,683 piculs, say a little over one million of pounds, to over 13½ millions in 1879. For 1882 the export could not be much less, as the estimates Mr. Ford obtained were

For Loting district ...	...	50,000 piculs,
„ Taiwu ...	...	32,000 „
Total...	...	82,000 „

say about 11 millions of pounds, without counting twigs. Can any of our readers, interested in cinnamon, supply us with figures shewing the imports into Britain of Ceylon cinnamon and China cassia for a series of years? No doubt an appreciable quantity of China cassia goes to other countries, but, as a good deal probably goes to Britain, we should be able in some degree to test the correctness of figures which have taken us utterly by surprize. Messrs. Russell & Co. of Canton and Hongkong, who supplied Mr. Ford with specimens of bark, &c., could, no doubt, supply valuable information as to the history of the rapid rise and progress in the past twenty years of a trade which has so seriously affected the cinnamon interests of Ceylon. Our exports of fine cinnamon, including chips, was for last season close on two millions of pounds. The exports of inferior cinnamon from China, the Eastern Archipelago, India, Burmah and all other producing countries (which, of course, supplied their own wants), must have been from seven to tenfold our exports. Mr. Ford's visit to the cassia districts was so timed that he arrived in the flowering season, so that he was able finally to solve the botanical question, and, besides a set of the instruments used in the process of decortication, he brought back plants, some of which were to be sent to other colonies. Dr. Trimen will soon be able to tell us if the China cassia is in reality anything more than a variety of the true cinnamon, influenced by circumstances of climate and culture. Indeed, the technical description given by Mr. Ford, which we do not quote, may settle this question. The probability is that China cassia bears the same relation to Ceylon cinnamon that China tea does to that of Assam. The largest tree Mr. Ford saw was 40 feet high: 3 in circumference with bark ½ inch thick. Some of the cinnamon trees in our forests are, perhaps, a little taller than 40 feet? There were no varieties of the one species, and it does not seem to grow wild in China, although it is said to be found in the forests of Cochin-China.* Mr. Ford has

"No doubt but that writers who have named other kinds as cassia yielding trees of China have been mistaken or misinformed on the subject. One writer alludes to a tree in terms which partly correspond to the description of *Machilus velutina*, Champ., another tree belonging to Lauraceae and indigenous to South China. It is quite possible that this tree may have been supposed by a casual observer to yield cassia bark because it is sometimes grown in plantations intermixed with those of *Cinnamomum Cassia*. The trees are reared, planted, and treated in precisely the same manner as the cassia trees, but the bark is required for a very different use, viz., to supply a glutinous extract which is used to stick together powdered cassia bark and sandal-wood—*Santalum album*—to form the joss sticks used for incense. *Cinnamomum Burmanni Bl.*, which it has been supposed may probably yield "in part the cassia bark of the Canton market" does not, I feel sure, supply cassia bark to any extent. I did not see it anywhere cultivated, nor was it seen growing wild in any but very small quantities, and these wild trees bore no signs of having been cut as had the cassia trees; many natives were asked if it was ever used, but, with one

* The statement in the *Encyclopedia Britannica* as to the export of "wild" cassia from China is contrary to what Mr. Ford states, and as Cochin China marches with China all probability is in favour of wild trees in the forests of both countries.

exception, all denied that it afforded any cassia bark. The one exception was an old woman, who was cultivating a field of Indian corn close to a few small trees of *Cinnamomum Burmanni*, and who said that its bark was sometimes, but rarely, used to adulterate the true cassia bark."

Thus did Mr. Ford solve the botanical problem and obtain valuable information regarding the important cassia industry in China. We do not quote the portions of the report which describe the mode of propagating the plant, as it does not essentially differ from the process pursued in the case of cinnamon. Neither can we find room for the detailed account of the general botanical features of the West River district, however interesting it is to scientific men. We may notice, however, that in China the cassia or cinnamon plant and pine trees (*pinus sinensis*) are associated.

After writing the above, we referred to the article "Cassia" in Simmonds' book and we find that, while 76,464 piculs of 133⅓ lb. of cassia were exported from Canton in 1872, only 1,363,000 of all kinds of spice were imported from China into Britain in that year. And probably most of the cassia imported was again exported. Up to 1870 only about 40,000 lb. of cassia per annum was consumed in Britain, cinnamon being preferred. We should like to know if there has been any change in public taste in the interval? And whether, on the Continent of Europe, Spain especially, Ceylon cinnamon is still used to flavour chocolate? For purposes of chewing by those who labour in quicksilver mines (under the idea that it counteracts the evil effects of mercury fumes), we should think the more pungent cassia is likely to be preferred.

From Simmonds' book on *Tropical Agriculture* it appears that even Messrs. Hanbury and Fluckiger shared the opinion which Mr. Ford has now dissipated as to the very varied origin of cassia, but they traced the bulk to species of *cinnamomum* prevailing from India eastward. While China supplies the world with the greater proportion of the inferior cinnamon called cassia, it is said to be produced in the Khasya hills in Eastern Bengal and exported from Calcutta. We extract as follows :—

"In this region there are three species of cinnamon, growing at 1,000 to 4,000 feet about the sea-level, and all have bark with the flavour of cinnamon, more or less pure; they are *Cinnamomum obtusifolium*, Nees; *C. pauciflorum*,, Nees; and *C. Tamala*, Nees. *C. iners*, Reinw. a very valuable species occurring in Continental India, Ceylon, Tavoy, Java, Sumatra, and other islands of the Indian Archipelago, and possibly, in the opinion of Thwaites, a mere variety of *C. Zeylanicum*, but, according to Meissner, well distinguished by its paler, thinner leaves, its nervation and the character of its aroma, would appear to yield the Cassia bark or wild cinnamon of Southern India. *C. Tamala*, Fr. Nees et Eberm, which, besides growing in Khasya, is found in the contiguous regions of Silhet, Sikkim, Nepal, and Kumaon, and even reaches Australia, probably affords some Cassia bark in Northern India. Large quantities of a thick sort of cassia have at times been imported from Singapore and Batavia, much of which is produced in Sumatra. In the absence of any very reliable information as to its botanical sources we may suggest as mother plants *C. cassia*, Bl. and *C. Burmanni*, Bl. var. *a. Chinense*. both stated by Teijsman and Binnendijk to be cultivated in Java. The latter species growing also in the Philippines, probably affords the cassia bark which is shipped from Manila (*Pharmacographia.*)

We can only repeat that during the period of Government monopoly of cinnamon in Ceylon, the Dutch managed to introduce the true cinnamon into Java, the cultivation of which extended while the Ceylon spice was burdened with duties so high at one time as 3s 6d per lb. Probably some of the product of the plants so obtained and cultivated is now exported as cassia. The United States, which take most of the Padang coffeee, get also some cassia bark thence. The position of cassia in the commerce of China is important, seeing that the exports of this article in 1873 were valued at $14,000,000, or fully 2½ millions sterling. The value, like that of cinnamon, has gone down in the period since 1873. The export of cassia buds from China has fallen off, and we find it stated that

In Southern India the more matured fruits of one of the varieties of *Cinnamomum iners*, Reinw. are collected for use, but are very inferior to the Chinese cassia buds.

The article on cassia in the new edition of the *Encyclopædia Britannica* is short, but it includes some interesting information, amongst the rest the fact that our fine Ceylon cinnamon is adulterated with and often superseded by the coarse cassia. To quote :—

The bark is imported into England in bundles, which are from 1 foot to 18 inches in length, and weigh about 1 lb. The bundles consist of quills of bark from half an inch to an inch in diameter, generally single, rarely double. The bark is much thicker than that of true cinnamon; the taste is more pungent and the flavour less delicate, though somewhat similar to that of cinnamon. A large quantity of thick, woody bark, of inferior quality, is now imported under the name *Cassia vera*, or Wild Cassia. The properties of cassia bark depend on the presence of a volatile oil—the oil of cassia, which is imported in a pretty pure state as an article of commerce from Canton. Cassia bark is in much more extensive demand on the Continent of Europe than in great Britain, being preferred to cinnamon by Southern nations. Both oil and bark are useful in medicine: but their chief use is for flavouring liqueurs and chocolate, and in cooking generally. When ground as a spice it is difficult to distinguish cassia from cinnamon, and it is a common practice to substitute the cheap common spice for the more valuable article. The adulteration may be detected by the behaviour of a decoction in presence of iodine, which in the case of cinnamon, produces little effect, but with cassia strikes a deep blue colour. *Cassia Buds*, which have a pleasing cinnamon flavour, are the immature fruits of the tree or trees which yield Chinese cassia. They are brought in considerable quantities from Canton, and used as a spice and in confectionery. Some confusion occasionally arises from the fact that *Cassia* is the generic name of an extensive genus of leguminous plants, which in addition to various other medicinal products, is the source of the senna leaves which form a most important article of materia medica.

The cultivated cassia itself has thus a rival in the bark of the wild trees, and the competition of both added to over-production accounts for the depressed position of the Ceylon cinnamon trade.

In an article on cinnamon in the local *Examiner* allusion is made to the extension of the culture in recent years under the influence of the high prices which then prevailed. Near Negombo fertile fields were converted into cinnamon gardens and the plant was grown on coffee estates upcountry. Of "chips" the record is :—

Keeping in view the fact that the exports have been swelled by chips—a comparatively new industry, unknown 20 years ago when only quills were prepared on estates—the Agricultural Association has taken steps to abolish, or even to restrict, the preparation and exportation of chips. When it is considered that scraping chips costs about 3 cents per lb. and that its selling price is about 7 or 8 cents, it will be seen that the producer nets only about 5 cents. This on 400,000

lb. the present annual out turn, represents about R20,000. If the withdrawal of this enormous quantity of inferior and woody stuff should have the effect of raising the price of the one and a half million lb. of quills now exported by one and a third cents a lb. the producer will be recouped for the loss of his chips.

The writer then proceeds to defend the combination to refrain from exporting chips. No defence is needed of what the growers have a perfect right to do, if they choose. We can only repeat our scepticism as to the agreement being observed and our fear that the hiatus created by the withdrawal of chips would be at once filled up by cassia bark. Cinnamon is bulky in proportion to its weight, and the article is so delicate and liable to damage, that it has to be stowed very carefully on board ship, passenger cabins being sometimes utilized for the purpose. But agitation for an alteration in the tonnage scale and for a reduction of freight and charges is perfectly legitimate. We can only hope that there may be a speedy revival in this ancient staple of Ceylon trade as well as in the newer products.

BRAZILIAN COFFEE.

The following letter has appeared in the London *Times*:—

Sir,—The late journals from England bring us news that representations have been made to Mr. Gladstone in favour of the adulteration of coffee with chicory and other like things.

If you will spare me the space I should like to write a few words on the growth and use of Brazilian coffee. As is generally known, Brazil produces about five-eighths of the whole coffee grown in the world, and it is on this product that the revenue of the Empire chiefly depends; hence an extended or restricted use of coffee affects very seriously the prosperty of this enormous country, only slightly inferior in area to the whole of Europe.

The coffee tree is not indigenous to Brazil, and the first notice we have of it is in 1723, when some few trees were sent to the province of Para, North Brazil, from Cayenne, French Guiana. The result of this experiment was unfortunate, so that we hear nothing more of coffee planting until 1773, 50 years afterwards, when a Franciscan monk of the convent of the Lapa, in Rio de Janeiro, planted a few trees, which throve so well that the then Viceroy used every endeavour to extend the planting of coffee in Brazil, which was then a colony of Portugal.

To grow coffee successfully it is necessary in the first place to have a suitable climate; next, the land must be rich and deep in good soil; and, lastly, constant attention must be given to the keeping down of weeds, which "grow apace" in these fertile regions. The coffee-growing districts of Brazil, although very rich and fertile in some parts, are in others so sterile that, were it not for the sweet influence of continual sunlight during the day and heavy refreshing dews at night, nothing would grow, not even the shrub growth and rank grass now covering them.

In Brazil the coffee tree is not annually docked and pruned as it is in Ceylon and Southern India, but it is allowed to grow naturally, so that at 10 to 12 years of age it is from 12 ft. to 14 ft. high, and it will continue to bear fruit for 50 years if only the dead branches are removed from time to time, and care be taken to prevent the trees becoming too much entangled. To form a coffee plantaton it is necessary to have rich, virgin, forest, soil, which when cleared of the timber by felling and burning, is planted with young trees about 11 ft. apart. These tender plants have to be screened from the sun during the day, and from any possible hail or frost at night, besides being kept free from weeds. The constant attention goes on until the little evergreen shrubs or trees are four years old, when they begin to bear fruit, which increases annually up to the eighth or ninth year, when the coffee tree may be said to be in full bearing.

From this it will be understood that any sudden demand for coffee cannot be satisfied, as five years are required for the formation of a plantation; and on the other hand a sudden disuse of it, caused by the imposition of taxes or other circumstances, is a most serious loss to the coffee-growing countries.

As I have stated, coffee, above all other things requires a suitable climate, which in Brazil is found chiefly between the 18th and 25th parallels, to the north of which is rather too hot, to the south too cold. Thus it will be seen that successful cultivation is limited to a comparatively small part of this enormous Empire.

Prior to the year 1800 little or no coffee was exported from Brazil, and up to 1840 the province of Rio de Janeiro was the only one that carried on a regular commerce in it; now, however, the adjacent provinces of San Paulo and Minas Geraes produce so largely that they rival Rio de Janeiro, making the total weight annually exported about 340,000 tons, which is five times greater than it was in 1840, and even this weight will not remain stationary, as new districts are being opened up and planted every year.

Withal the increase the production of coffee has been so great, it has not been out of proportion to the increase in the consumption of coffee—too often so called, being in reality only a wretched beverage made of chicory, rice, burnt beans, Indian corn, fruit seeds, &c., which falsifications and adulterations have grown and are still growing so enormously that they are beginning to tell seriously on the price of coffee; so much so, indeed, that the planters now receive little more than half of what they did from 1876 to 1879. Other circumstances may have helped to bring about this state of things, but there is no doubt that the chief influence working against the price of coffee is the unfair adulteration carried on in the London markets and in the large continental centres. Every one ought to be allowed to make and drink any and whatever abomination he may think fit, be it made of sawdust or horse-beans, but it is exceedingly unfair that the consumer should be obliged to pay for coffee (which besides being pleasant to the taste is stimulating to the body) and then receive some adulterated stuff which has no virtue beyond the stolen name of coffee.

The English taste is inclined to the strong and perhaps to the rancid, as evinced by the preference given to strong meats, strong beer, stronger port, and strong cheese, and the use of chicory mixed with coffee. Being so, when catering for our countrymen this fact must be taken into consideration; but why is it, that loving a strong flavour, they, when they take coffee, will not take it strong and pure, a little of it, instead of a pint of fluid the colour of pale ale?

The use of strong pure black coffee as a stimulant when the body is run down through physical labour is almost unknown in England; whereas it is a fact that it is one of the best, and at the same time the least noxious to health, of all the beverages which spur jaded humanity to further exertion.

Hundreds of days have I tramped through swamps and entangled brushwood when shooting in the province of San Paulo, using as a stimulant at midday only a small cup of strong black coffee made from beans that had been kept for two or more years. At these times a cup of this beverage would brace me up as much or more than the wine or beer taken by my companions, and no one can say he ever saw me lag

behind or refuse to stalk that last snipe, although it was necessary to drag through a swamp for 500 yards or more. This experience of mine is borne out by others who have travelled into the interior of Brazil, where the choice lies between a cup of warm sweet coffee and a draught of sugar cane rum, the smell of which to any but an old resident is, to say the least of it, painful. Beyond this stimulating power, coffee has great disinfecting properties and is used by many who have to travel throug miasmatic districts as a preventive against fevers. The Rev. Father Kenelm Vaughan, but a few years back made a journey by land from Panama down to the River Plate, passing in and among and over the Andes during a space of three years, used coffee only as a stimulant, although he had once to run the gauntlet through a long rock-bound valley in Colombia, in which the water remained stagnant year after year, and the narrowness of the gorge prevented sufficient sunlight and heat entering to dispel the vapours. I asked him what he took in this horrible place, called by the natives by the significant name of "Valley of Death," to which he replied, "Why, coffee, of course!" This same gentleman also tells me that since the natives in the pestilent districts near Guayaquil in Ecuador have substituted coffee for their former beverages the death-rate has fallen very considerably.

Surely the retailers of burnt beans, Indian corn, and other things falsely called coffee do not presume to claim such high honours for their decoctions. Then, why should the honest artisan or labourer be compelled to pay a high price for things which can have no other recommendation or virtue than that they are fraudulently called coffee?

Now, as to the price of coffee, there must be something seriously and radically wrong in the English market for although the price received by the growers has fallen almost to one-half of what it was from 1876 to 1880, and the production has increased enormously, the price has not fallen correspondingly for the retail buyer, who still has to consider coffee as an expensive luxury and one which has, therefore, to be mixed with chicory and other adulterations.

Brazilian coffee has been unfairly abused in England and on the Continent, owing to the merchants selling the best washed Rio and Sao Paulo coffee as that of either Mocha, Ceylon, or Java, whereas the inferior coffees of other lands are too often called Brazilian. To remedy this gross unfairness would be difficult, but as "the proof of the pudding is in the eating," so with the drinking can coffee be proved. Brazilian coffee can stand this test, as is proved by the fact that the coffee sent by Englishmen here to friends at home has been declared by one and all to be delicious, and why not?

Brazilians, as a rule, do not prepare their coffee for the market so well as the Ceylon and Java planters do, but even this reason is not sufficient to explain the non-using or disliking of Brazillan coffee, which, when the bean is badly prepared, has a slightly bitter flavour which ought to be appreciated by the mass of Englishmen. This bitterness can be very much lessened by keeping the coffee beans; in fact all coffees ought to be kept for more than two years before being used. Still supposing this tempering through time could not be atrived at conveniently, there is no reason why an Englishman should not enjoy that which our American friends in the States pronounce "excellent." Surely, it seems as if fashion and the tricks of trade even go so far as to govern our palates and our prejudices.

As a last, but by no means the least important point to be remembered when advocating the use of pure coffee is that in coffee lies the hope of the temperance societies of being able to drag our many thousands of drunkards away from their death-dealing, misery-spreading vice, by giving them a stimulant which is agreeable to the taste, but which will not intoxicate; these societies, therefore, should urge the Government to oblige the sale of unadulterated coffee, upholding Mr. Gladstone in his noble attempt to give his countrymen another real blessing.

The difficulties in the way of the Government in prohibiting the adulteration of coffee are, indeed, many, such as were found in 1852, when the Government by a Treasury minute tried to stop adulteration; there can be no doubt, however, that if penalties were attached to the adulteration of coffee, the bulk of the respectable trades-people would at once conform to the law, leaving the chicory, dates, and other coffee falsifiers to take care of themselves. If these suffered there would be at least the consolation of knowing that ninety and nine would be benefitted, and the hundredth would only be rewarded according to his works.

I am, sir, your obedient servant,

Walter J. Hammond,

Engineer and General Manager Western of Sao Paulo, Railway Company.

Jundiahy, Province of Sao Paulo, Brazil, July 28th, 1882.

THE LONDON "TIMES" ON COFFEE.

Englishmen, as a Persian traveller has remarked, do not worship the sun, probably because they have never seen the sun. Their want of devotion to coffee may be explained in the same way. The majority of Englishmen have never tasted anything that deserves to be called coffee. Only a few of them have ever tasted the best coffee. Coffee has been on its trial in this country for more than two hundred years. It has had its ups and downs. It was received at first with great favour, but by a very limited number of customers. By and by the custom of coffee-drinking spread. Coffee-houses grew and multiplied, and were frequented by persons of every class, no one, as Macaulay tells us, being refused who could lay down his penny at the counter. It seems that, to a certain extent, the ill-fame attached to them of being a resort of disaffected persons and centres of disturbance to the peace and quiet of the nation. We should hardly recognize the modern coffee palace under such a description as this. It has come to be regarded as an adjunct of social order, a mainstay of the temperance movement, and so far worthy in every way of the support its promoters claim for it. If there has been a falling-off anywhere, it has not been in the coffee-houses and their frequenters, but in the coffee itself. The berry which Charles II. denounced, and which he seems to have hated much as his royal grandfather hated tobacco, was at least good of its kind. In those early days of coffee-drinking, Mocha coffee had a monopoly of the market. But as the demand for coffee increased, the supply of Mocha coffee soon fell short. The culture in consequence was extended. The attempt to grow coffee outside Arabia was made first in the Dutch East Indies, then, early in the eighteenth century, in the West Indies. Since that date the coffee plant has been introduced into almost every tropical country, and it has flourished everywhere both in the old and in the new world. But whether quantity and quality have kept pace together is another question. Experts tell us that they have not; that good Mocha coffee is as distinct a thing now as it ever was, and that those who have not tasted it simply do not know what good coffee is. Englishmen, we are told, can order the best Mocha coffee; they can be served with something which bears the name; they can pay highly for it; they can do everything but get it, and this, we are assured they never do. All the best coffee which the Yemen district produces is kept for use in the East. Before it moves westward it

has been carefully picked over, and the choicest berries have been subtracted from it. It is only what remains after this process has been again and again gone through that it ever reaches England. But most of our Mocha coffee has even less title than this to the great name it bears. Mocha coffee, like Havannah cigars, can be grown anywhere, and with those who have never tasted the genuine product the imitation will pass. A letter which we printed on Wednesday from Mr. W. J. Hammond, of the San Paulo Railway Company, complains bitterly of the fraud. Brazilian coffee is discredited by it. The best is sold as Mocha coffee, or Ceylon coffee, or Java coffee—honourable names all of them. What is known in the market and is confessed to as Brazilian coffee is the inferior sort mixed with the inferior coffees of other countries, and it is from this bad compound alone that the coffee-producing capacities of Brazil are judged. It is the English consumer, we think, and not the Brazilian producer, that has the more real reason to complain. The producer commands his market and gets his price from the middle man. The consumer pays for what he does not get; and whether he is put off with good Brazilian coffee as best Mocha, or with refuse coffee as best Brazilian, he is a cheated and an injured man.

But it is in the art of making use of his coffee when he has got it that the Englishman is most notoriously wanting. Coffee-making as commonly practised in this country, combines almost every imaginable fault. The coffee berry has not been freshly roasted. It has very seldom been freshly ground. Most probably it has been bought in a ground and, therefore, in an adulterated state. Chicory and beans and beetroot are the least objectionable of the many abominations which have been mixed with it. The tradesman who sells it may quiet his conscience with the reflection that the man who is capable of buying ground coffee must be so utterly ignorant of the very rudiments of his art that pure material would be wasted upon him. So in the result, it proves. The next step in English coffee-making is to put a very small amount of coffee into a large pot and to set it on the fire until it boils. Whatever the original material may have been, boiled coffee is spoiled coffee; and weak coffee, boiled or unboiled, can never be worth drinking. Now, most of the above faults can be avoided with a little care and a little elementary knowledge. We will not be purists enough to insist that the coffee berry must be bought raw and roasted on each occasion for the day's use. This is the best plan, of course, but it is a very difficult and very troublesome plan to follow, and there are very few English servants who could be trusted to succeed in it or even to try it. But grinding coffee is a humble art within everybody's power of attainment. This at all events must be done, and the coffee when it has been ground must be used without delay, and must be used liberally. It must not be pressed down and it must not be boiled, but boiling water must be poured upon it very slowly, almost drop by drop, and must be allowed to trickle slowly through it into the lower half of the percolator. It is a troublesome process, but it is the only one from which really good coffee will come. Those who are content with what Mr. Hammond terms a pint of fluid of the colour of pale ale can go to work in their own way, and can be pretty sure of getting something that will satisfy them. But they must not call the stuff they drink coffee, or at least they must make no attempt to palm it upon their friends as coffee, for this most assuredly it is not. The man who knows what good coffee is will very properly resent being put off with a counterfeit so bad and so unlike the real thing that the mere offer of it is an insult to his understanding or his taste. As for the various imitation coffees which are commonly sold or commonly exposed for sale—for we do not know what sale they command—the purchasers, if any, must take them at their own risk. Good coffee extract is a convenient thing, ready and handy for use. It makes an agreeable drink enough, but it does not make coffee. Date coffee, with which Mr. Hammond is more angry than with the rest of its class, scarcely deserves the hard names he has for it. A cheat we cannot call it. It is not made from the coffee berry, and it does not pretend to be. That it has not the properties of coffee is put forward as a recommendation for it, and the fact is vouched by respectable medical authorities. The most delicate subjects may use it, we are assured, with perfect safety. No cerebral excitement will come of it; no attacks of nervousness; no sleepness nights. It would really seem, on the vendors' own showing, that "except for the glory of the thing"—as the Irishman said about his sedan chair that had no bottom to it—we might just as well not be drinking coffee at all.

Coffee and tea are natural allies, but they are also natural rivals. As against alcoholic drinking in any form they are combined. It is over the unoccupied territory, after alcohol has been driven away, that the contention between the two comes. Taking the world through, the general verdict seems to be in favour of tea. Two of the largest empires in the world, China and Russia, are tea drinkers. In Bokhara and Samarcand, and in most parts of Central Asia, the tea urn is for ever steaming. On the other hand the Arab and the Turk, and with them the whole Western part of the Mahomedan world, are coffee drinkers. The decision of Europe is not absolute for either side. It seems to be very much determined by what we may call the accidents of the case. The nations which can get good coffee drink coffee. Those which can get good tea drink tea. Those which can get both drink both. England claims to be one of these, but the preference of England is beyond all doubt for tea and not for coffee. The unfair choice is very largely compensated for in the United States—the chief coffee-consuming country in the world. Englishmen, too, would probably make more use of coffee than they do if they could once be induced to overcome the initial difficulties of having it prepared as it ought to be. Tea can be made easily enough. It may be strong or weak according to fancy. It is tea in either case. The right plan, we are assured, is to put plenty of tea into the pot, then to add a little more tea; and, this done, to leave it to chance whether the liquid comes out strong or weak. But whatever we may think of weak tea, there is no good word to be said for weak coffee. Coffee must be very strong if it is to deserve the name of coffee at all. It is a generous drink, and it is for generous natures. The little arts which the frugal housekeeper uses in making tea are not to be thought of in making coffee. There must be no economy in the amount used, no filling up the pot; no making the same materials serve twice over. That tea should ever be made like this is bad enough, but there may be tastes so depraved as to put up with it and to see nothing to object to about it. The man has yet to be found who can even make pretence of liking weak coffee, diluted into ten times it proper volume and as deficient in fragrance as in strength.—Sep. 9th.

THE COCONUT PLANTATION of Mr. Asmus on the Endeavour, North Queensland, looks remarkably fresh and healthy (says the *Cooktown Herald*), the trees, although only two years old, averaging 8ft. in height. In five more years the spirited proprietor will begin to reap a rich harvest, which, without so much labour as is attached to preparing soil and removing cereals, will be continued for probably forty years.—Melbourne *Argus*.

COFFEE PLANTING IN CEYLON:

IS "ICHABOD" TO BE WRITTEN ON THE COFFEE ENTERPRIZE OF CEYLON, BECAUSE THE GLORY HAS DEPARTED?

Our correspondent "G.." (on page 465) who has written on "Ceylon revisited," would answer in the affirmative, except as to a few highly-favoured districts. We cannot help asking whether he and his despairing friends who cry "One year more and then ——?" do not take too pessimist a view of the situation. Our correspondent has been naturally struck with the altered conditions of districts such as Pussellawa and Ramboda which he remembers in their glory, but has revisited in the sear and yellow-leaf and worn out soil of their decay. But those districts yielded fortunes in their day; and even if leaf-disease and abnormal seasons had remained absent, from effluxion of time and the hoeing and scraping system of weeding, their present case might not be much better than it is. And even as to the old and effete districts, as far as coffee is concerned, it is gratifying to learn of the probability of new leases of life as cinchona and tea plantations. (Our correspondent did not visit the region in which cocoa is flourishing.) This was just what Sir Wm Gregory said, when he described coffee as "precarious" "Even if coffee entirely failed," said our late Governor, "I never meant to indicate that Ceylon had come to the end of her tether. It is impossible to predict the number and the value of other products for which the climate and soil of the island are suited, and which can yet be cultivated remuneratively." The shrewdness of Sir William's vaticinations have been fully confirmed, and, although the new products introduced and growing associated with or in supercession of coffee, have their own leaf and root diseases and other drawbacks, yet the prospect to the manful, careful, sagacious persevering fighter of the battle of planting life seems fairly promising. Another old planter, whom we should gladly see revisiting Ceylon, thus alludes to the mistakes of the past—in the direction of extravagant purchase of land and costliness of management—and the prospects of the future of men taught by the bitter but wholesome lessons of adversity, writes to us as follows:—

"I am really hopeful for the future of Ceylon, but a new generation of planters must arise free from the painful recollection of the fatal bungling which led to the collapse of coffee planting. £20 an acre for jungle! £20 an acre for 'cultivation'!! &c., &c. Looking over some old reports the other day, I found how urgently Mr. —— (not now in the island) wrote to certain proprietors recommending not to *fell* another tree 'till we see the result of this blight.' 'Why not?' was the ready reply, 'you say the jungle is worth £5 an acre, but I can get £50 if planted; and the argument was not easily answered; altho' I did think it would lead to disaster, but *did not think* the disaster and *disgrace* would come so soon and be *so complete*.

"While writing this to catch the out-going mail, who pops into my office, but our good friend, —— he shows me his bill of sales and certainly, his prices for cinchona bark (5s 6d and 6s per lb.) puts a new aspect on Ceylon matters. With Tea as the backbone and Bark as the right arm, with land at £1 an acre again and planters purged of their idiotic ideas of their 'powers of financing' and fabulous value of estates, there would be a bright future; till adversity has taught this lesson, there is not."

We are glad to learn that the gentleman alluded to has been as successful with coffee as he has been with cinchona, and that his case is by no means singular. From what a coffee planter told us this morning of his own case, we suspect it will be many years before the epitaph of old king coffee has to be written if ever. An average yield of 7 cwt. per acre of coffee over 300 to 400 acres maintained to the end of last year, by the aid of bones and poonac, judicious and timely handling and pruning, seems too good a report to be correct; but such is the statement made to us in reference to a property in a favourite district not 60 miles from Kandy, with the offer to verify it by "the books." At the same time, our informant (any more than ourselves) would hinder no one from doing all in his power with "new products;" but he probably would unite with a well-known Dikoya proprietor lately returned to Ceylon, in saying "Do not spoil really good well-cared-for coffee by turning it into a cinchona field." These gentlemen and others believe that, after this prolonged wet monsoon, an exceptionally dry and favourable blossoming season with a good coffee crop will follow; but then there are those again who answer this by saying, "Yes, and it will be the LAST good crop"! Amidst all the depression, it is cheering to know that there are hardheaded men of experience amongst us, who have no fear of being able for years to come, to fight leaf disease and cultivate coffee profitably, more especially when supplemented by belts or fields of cinchona, cardamoms, or cocoa and tea. What with so many alternative resources we do not think there is any reason to fear for the future of planting enterprize and Ceylon. It is possible that "RESURGAM" will be the appropriate inscription even for coffee, rather than "ICHABOD."

TEA CULTURE IN TRAVANCORE.

Although a successful trial with tea was made in Travancore many years ago, yet up to last year the progress made with this cultivation is represented by such insignificant figures as the following:—

Mature plants	... ...	71 *acres*
Immature	... ...	103½ ,,
Taken up but not planted	...	36 ,,
Total...	...	210½ ,,

The approximate yield of tea in 1881 was 9,300 lb., the average per acre of mature plants being only 135 lb. Of course, if nothing better than this could be got, the planters have done wisely in avoiding the pursuit: but the average is between 0 in one district; 300 lb. in a second and 41 lb. in a third, while in three out of four estates the plants were allowed to grow to seed. The tea was grown at elevations varying between 2,175 and 3,650 feet. We suspect that before 1891 comes round very different figures will have to be used to represent the tea cultivation of the Travancore State.

SERICULTURE IN TINNEVELLY.

(*From a Correspondent.*)

The following details of the silkworm industry of Tinnevelly were taken down directly from an old native, who lives by their culture. He states that the silk worm, *cumbly poochi* or *pattu poochi* is not indigenous but was brought here long ago. The first step in the production is to get the male and female moth and leave them together. In about ten hours the female begins to deposit eggs. The

male is then taken away and killed. The female finishes laying in about fourteen hours and then dies. The eggs are kept carefully in the house, not exposed to the sun. In ten days the hatching is complete; as soon as the worm appears it must be fed with (mulberry) leaves. The worms must be fed eight times in each day of twenty-four hours. This feeding must be continued for a space of twenty days, with the exception that on every fifth day they get no food at all. Our old native told us the worm suffers from fever on these days, *i. e.* four days in twenty, and no food should be given on the fever days. On the twentieth day the worms are developed into light yellow wriggling beasts about two inches long. These are fed for a further period of ten days. During this period they have no fever. After the tenth day they are "ripe" and eat nothing more. They are now of a distinctly yellow colour. They are put into a wheel-like cage, called in Tamil "senthurukum," where they are kept for about twenty-four hours. During that time they spin the cocoons. A few are now selected to keep up propagation. After ten days the male and female moths emerge from the cocoon and the process recommences. The cocoon from which the moth has come out in due course of nature is useless for spinning purposes. To get the silk, the cocoons are kept only some six seven or eight days instead of ten; they are then thrown into a boiler containing hot water; a small fire is kept up to ensure the requisite temperature, *i. e.* rather hotter than the ordinary hand can bear, though the practised hand of the operator goes in and out freely. The operator sits on the top of the boiler, selects a couple of good threads and fixes them in the first catch of the spinning machine; one boy feeds the fire and another turns the handle which supplies the motive power of the machine. The operator stirs the parboiled poochies and pays out the thread through his fingers. The cocoons unite together of themselves in the water in some curious manner. When a sufficient quantity of silk has been spun off it is rolled into a twist, the price of which is about a rupee a pallam, when this is cleaned by the buyer, who is generally a weaver, and connnected with the weavers of Koravad in Tanjore; it weighs from ½ to ¾ pallam. This purified thread is worth R3 a pallam, and is sold to merchants who weave it, or supply it to the weavers. The poochi breeding industry goes on all the year round, unless checked by a failure of the requisite leaves. The man we interviewed paid his two assistants and also the people who cultivated his leaf fields. He rented the lands, *i. e.* he did not himself hold puttas for them. His clear monthly profit was between five and six Rupees on an average. He had no other occupation There were five families in the village who followed this calling. There is only one other village in the district where the industry is practised. The names of the villages are Melagaram and Samiar Kudrijiruppu, between Courtallam and Tenkasi.—*Madras Mail.*

THE COCA LEAF MASTICATORY AND YERBA MATTEE TEA OF SOUTH AMERICA,

form the subject of a very interesting communication from Mr. Wm. Blackmore, senr., dated from Holyrood Tunnel, on the Nanuoya Railway Extension. Mr. Blackmore gives the results of his personal experience, and it seems that as in the case of the betel leaf and areka masticatory of Ceylon and the East generally, fine lime is used to act chemically on the vegetable matter and their juices. But we believe that in this part of the world the narcotic stimulant is not specially used at high altitudes and intermitted on the plains; quite the contrary, we imagine. The following is what Mr. Blackmore writes:—

"On three or four occasions I have seen notes respecting coca leaf and its uses and sustaining qualities in your paper. As I was two years and four months at Cerro de Pasco in Peru, making a railway to the silver mines at an altitude of fifteen thousand feet, I have had to assist in giving 700 labourers their coca each morning. For a day's allowance they get just one handful. They march to their work, sit down about 20 minutes to chew their coca leaf with which they mix some fine flour lime, which they carry in a very small calabash bottle and take it out with a small stick, after wetting the point This they put into their mouth in order to mix the lime with the leaf. They commence work at 8 a. m., work till 11-30, when they have half-an-hour, during which they eat a few scorched grains of maize. The old quid is thrown away and a new one put in its place. They again work till three p. m., when they take fresh leaves without the maize. The same is done at night with a few scorched grains of maize or beans. This is almost the sole food they get, and considering the altitude where respiration is so difficult, they work remarkably well. Indeed they are a far superior class of workmen to the coolies of Ceylon. During my residence in Cerro de Pasco I made the acquaintance of an Englishman who had been in the country 20 years and a great part of that time he had been an officer in the Peruvian army. He told me that the soldiers with half-pound of coca leaves and about a table spoonful of fine lime, would march from Cerro de Pasco to Lima. 150 miles, without any other food; but I have also been told there that those who use it in the mountains leave it off if they reside on the coast for any time, so that it must be most beneficial in great altitudes. I frequently used it myself by putting a handful in the tea-kettle instead of tea. It is a very good tonic: in fact I got to like it very much. I was also six years in Uruguay, Banda Oientale, making a railway; Yerba mattee was used by all classes. In fact I brought several lb. of Yerba mattee to Ceylon with me, but in moving from Hogg's Back to Blackwater it got wet and spoilt, I forgot to mention that coca grows on the upper Amazon, where it is gathered similarly to tea, the leaves of which it very much resembles. The leaves are dried, and then they are packed in bullock's hides, sewn on each side while still wet and they are packed so tightly that as the skin dries the tea becomes almost as hard as a stone."

BLUE GUMS AS BREAK-WINDS AND THE GUM LEAF-DISEASE.

Dr. Trimen is to be deputed to examine into and report on the, apparently, obscure disease which has attacked the gum trees and from them spread with injurious effect to cinchonas and other trees. We hope, therefore, soon to have reliable information as to the nature of the disease and the remedial measures which may be possible. Dr. Trimen will, no doubt, direct his special attention to the alleged immunity of trees so young as to have only the original foliage on them, or which have retained that original foliage (very distinct in size, shape and colour from the secondary crop of leaves). in consequence of having been topped. Extensive breakwinds of trees topped as the late Dr. Thwaites recommended, exist on Inverness Estate, (which is separated from Abbotsford only by a belt of jungle), and it will be very interesting and important to learn if such trees have

escaped. The great enemy of tea as well as cinchonas in Java is *helopeltis Antonii* (known in India and dreaded, next to "red spider," as the tea bug). But this formidable insect makes its presence known, not only by its own teeming abundance, but by punctures in the leaves which it attacks. But neither have the insects been seen, nor punctures in the leaves noticed, on either gums or cinchonas at Abbotsford. We have heard of cinchonas suffering from the identical disease, which were not in near proximity to gums, and this also is a point to which Dr. Trimen is sure to give his best attention. It is not likely that we or the superintendent of Abbotsford, who is part owner of the estate, should exaggerate the evil effects of the new pest. Exaggeration is simply impossible, and the one question we are anxious to see solved is whether the fast growing and, therefore, valuable gums are so clearly the *fons et origo* of the evil, that it will be a clear duty to sacrifice them and the shelter they afford, in order to save still more precious cinchona and tea plants. *Grevillea robusta* is a most valuable tree for shade and timber and we have never yet heard of its liability to any disease. But Dr. Trimen will doubtless examine and report on the whole of the Australian *Eucalypti* and *Acacias*, and also other trees grown on estates, as breakwinds or otherwise.—We are aware that the gum leaf-disease exists on several estates in Dimbula besides Abbotsford, and also in Dickoya, but, without permission, we do not feel at liberty to mention the name of any place save the one we are specially interested in.

COFFEE CULTIVATION IN TRAVANCORE AND COCHIN

We reprint, from a paper received from the Madras Government, a statement of coffee culture in the feudatory states of Travancore and Cochin omitting the names of five districts in Travancore, from which no returns were received from the planters, although repeatedly called for by the Dewan. The table, therefore, is incomplete, in the sense of being, probably, much below the truth, for out of 11 districts in Travancore in which coffee appears to be cultivated, returns are given only for 6, or a little more than one-half. Taking the figures as they stand, we find that 74 plantations in Travancore, situated at altitudes varying from 642 to 3,560 feet comprised 6,999 acres of mature plants; 721 of immature, and "taken up, but not planted," 6,925; the total area being 14,645. The approximate yield in pounds was 1,815,050, giving an average for the portion containing mature plants, of 259 lb per acre. The cost of cultivation is given at the moderate figure of R38 per acre "for the province," which shews that manuring has been as much intermitted in Travancore as in Ceylon. The average yield it will be observed, is not much over 2 cwt. per acre. The statement, so far as it goes, seems to confirm what we have heard, that the coffee enterprise in Travancore has suffered much more than in the Wynaad, Coorg and Mysore. For Cochin, the returns are for the whole State, which contains 16 plantations at an average elevation of 3,000 feet, with 1,500·5 acres of mature plants; 700 acres immature; 5,501·5 taken up but not planted: total 7,709. The approximate yield in lbs is given at 465,155; the average per acre of mature coffee at 310 lb and the cost of cultivation per acre at only R22. In the State of Cochin, therefore coffee would appear to yield better at less cost of cultivation than in Travancore; but comparison is vitiated by the absence of complete returns for the larger State.

Statement illustrative of the state of Coffee Cultivation in the Travancore and Cochin States for the year 1881.

	Number of plantations.	Approximate average elevation.	Area in Acres.				Approximate yield in lb.	Average yield in lb. per acre of mature plants.	Cost of cultivation per acre in the province.
			Mature plants.	Immature plants.	Taken up for planting but not yet planted.	Total.			
Travancore.			Acres.	Acres.	Acres.	Acres.	lb.	lb.	R.
Thovallay	13	From 1,338 to 2,015 feet.	1,135	12	190	1,337	224,956	198	37
Culcolam	14	,, 642 to 1,467 ,,	2,349	26	914	3,289	563,107	239	27
Nedoovengad	5	,, 1,900 to 3,560 ,,	490	...	830	1,320	129,270	263	43
Kotarakurry	1	,, 1,000 to 3,000 ,,	365	...	200	565	133,400	365	50
Meenachel	27	,, 2,278 to 2,574 ,,	1,944	461	4,583	6,938	558,113	287	45
Chenganacherry ...	14	,, 1,357 to 1,500 ,,	716	222	258	1,196	206,204	288	28
Total ...	74	... ...	6,999	721	6,925	14,645	1,815,050	259	38
Cochin ...	16	3,000 feet.	1,500·5	700	5,501·5	7,702	465,155	310	22
Tot 1 Feudatory States	90	... ...	8,499·5	1,421	12,426·5	22,347	2,280,205	—	—

The totals for the two States must be larger by at least 25 per cent we should think than those given in the table, viz :—

	acres.	
Area under mature plants,	8,499·5,	yielding lb. 2,280,205
,, ,, immature ,,	1,421	
Taken up but not planted,	12,426·5	
Total, *acres*	22,347	
We should estimate,		
Acres in coffee, at least	15,000	
Taken up but not planted	30,000	
Total, *acres*	45,000	

And the yield of coffee, about lb 3,000,000, or say cwt 27,000 in round numbers.

COFFEE.

TO THE EDITOR OF THE LONDON "TIMES."

SIR,—The letter on coffee in *The Times* of the 6th instant cannot be too widely read.

The coffee trade of this country ought to have a great future before it by largely increased consumption, but while chicory is allowed to be added in any quantity, so long as it is sold as a mixture of coffee and chicory, and as police reports show frequently 75 per cent. chicory (value about 3½d to 4d per lb.), no wonder the public decide against the so called coffee at prices from 1s. upwards.

Vendors of these mixture should be compelled to state by a plain label on each package the proportion of coffee they contain. This would at once cause the consumer to purchase coffee and chicory separately and the taste for coffee would rapidly increase. Comparatively few now ever taste a cup of good coffee, and even those who do so at home are afraid to order it as a beverage when away from home, knowing the risk they run of being served with some unpalatable mixture.

September 7th. Yours truly GROCER.

TO THE EDITOR OF THE LONDON "TIMES."

SIR,—Since the subject of Brazillian coffee has been brought forward I should like to be allowed space for a few more remarks upon this staple production of one of the largest empires in the world.

The washed coffee referred to in *The Times* of today by "A shipper of Thirty Years" has a certain resemblance to Ceylon coffee, but the fact of its being equally good is very questionable. The Brazilians themselves disdain to make use of this style of coffee as a beverage, and its sale in London is probably owing to its favourable appearance allowing it to be successfully mixed with Ceylon coffee. Washed coffee, *café lavado* or *café despulpado*, forms a very small fraction of the Brazilian crop, by far the major portion undergoing a different process of preparation altogether.

The coffee-growing land of Brazil extends over such a large tract of country and diversity of soil that a great variety of qualities are obtained. The United States are chiefly supplied from Rio de Janeiro, where the coffee, strong and bitter in taste, contrasts markedly with that exported from Santos, whose product, in North America, comes under the head of mild coffees.

The earthy taste spoken of by your correspondent is scarcely attributable to its being left on the ground after falling, as the coffee is picked from the trees and spread out to dry on a "terreiro" or large drying ground of beaten clay, and the colour and taste of the bean are mainly dependent on the amount of dust it contrives to pick up while in this situation.

One peculiar feature of Brazilian coffee is its quality of improving by age, the native epicures never drinking coffee that has not been kept for two or three or more years; how far this peculiarity is due to the evaporation of rank essential oils I am not prepared to say.

It is only reasonable to suppose that Brazilian coffee will eventually be more largely consumed in Great Britain since the supplies from Ceylon are rapidly decreasing, and, from what the Americans say, its Costa Rican and Central American rivals are already feeling the low prices a serious hindrance to lucrative production.

On the Continent Santos coffee evidently finds favour, witness the large shipments to Havre, Antwerp, and Hamburg, and indeed, were it better known, I think the British would prefer the delicious, aromatic flavour of good old Santos coffee at 40s per cwt. to the equally expensive compounds of chicory, &c., or the hypothetically greater excellence of Ceylon and East Indian at a cost more than twice as great.—I am sir, yours truly,

September 7th. YPIRANGA.

TEA.—In the Consular report on the trade of the Persian Gulf, the following remarks occur, and are worth the attention of the Calcutta tea Syndicate:—"There has been an introduction of tea from Japan into Persia, which is said to find much favour. In former times Persia received tea through India from China, and supplied Russia; later, owing to prohibitions, Russia commenced to supply Persia with tea brought overland from China into Russia. The Indian teas seem little known in Persia hitherto."—*Produce Markets' Review.*

FROM experiments recently made, it appears that the rêh soil prevalent in some places in in the North-Western Provinces, can be utilized for the manufacture of caustic soda for paper making purposes, and that as good caustic liquor can be made from it, as any that comes from England. Papermills in this country must doubtless import a large amount of caustic soda from England for the manufacture of paper; but a considerable saving in this respect could perhaps now the country, were utilized for the purposes of paper-making. The Upper India paper mills at Lucknow are making caustic soda from rêh and success has attended its efforts. The Government of India has brought the subject to the notice of the several paper mills and have invited opinions on the feasibility of so utilizing rêh soil.—*Indian World.*

SOUTH-WEST WYNAAD.—A correspondent writing from the subranges of the Nilgiris, states:—"Like yourselves we have suffered heavily in the valley during the past monsoon in the matter of cinchona, mostly this and last year's planting and notably so at 3,000 feet, where the land is flat and the subsoil retentive; in some cases over 50 per cent. On steeper land at an altitude of 4,500 feet. our loss does not exceed 5 per cent. and not 1 per cent. amongst 3, 4, and 5 years old plants. Our rainfall up to date averages from 140 to 180 inches against a yearly average of 85, and yet with this heavy fall coffee is looking splendid: not a speck of leaf-disease from one end of the valley to the other. About two months ago we had a little on your old friends the "chic." These are now looking well and full of vigour, but no crop unless on Hope, where some of them are bearing at the rate of 3 tons an acre." [*Tons*, while a big crop in Ceylon this year is 3 *cwts.* per acre!—ED.]

WOOD FOR TEA BOXES.—*The Indian Planters' Gazette*, referring to a letter from Mr. Horsfall to the editor of the *Ceylon Observer* writes:—"The veriest tyro in tea knows that the utmost care is necessary in selecting wood for boxes. In Upper India the chir (*Pinus longifolia*) was tried simply because it was plentiful and easily worked, but its resinous smell was fatal to its use, and planters had to fall back on mango wood. Toon wood is admirably adapted for this purpose, but its price is prohibitive. Whatever wood a planter uses, he must avoid that which emits a strong odour, either pleasent or otherwise." Regarding our suggestion of paper tea boxes, the same writes:—"There is really nothing out of the way in this idea *Papier mâche* is, when properly made, water-tight, and that it possesses strength as well is shewn by its being used in America for locomotive wheels. It has also the two great advantages of being perfectly free from smell, and of being extremely light. A worse thing might be done than trying our contemporary's suggestion."

Correspondence.

To the Editor of the Ceylon Observer.

COFFEE AND LEAF-DISEASE IN FIJI.

Levuka, 25th August 1882.

SIR,—In a recent issue of your paper, there was an article upon the subject of Mr. Storck's cure for coffee leaf-disease to which you added the following note:—"'Physician cure thyself' is an old proverb, but Mr. Storck has not killed leaf-disease in Fiji, where it is really virulent." I don't know from whom you obtained your information, but whether or not it is correct you can judge from the following:—Some time ago I applied to the owners of two coffee estates in Fiji for permission to try Mr. Storck's remedy on their properties. The reply I received from the owner of 100 acres was that he was not afraid of the disease and he thought it would do him no harm; but as a favour he would allow me to experiment upon *one acre only*. The reply from the owner of 350 acres stated that "the disease existed only to an inappreciable extent as regards any injurious effects. He did not wish to pick any greater crop, for his trees were bearing just as heavily as he cared to see them, and, as the disease did not affect the quantity or quality of the crop, he should be inclined to spend any sum, however small, in manure to fortify their bearing capacity."

The general opinion in Fiji about leaf-disease is similar to the above and scarcely any one is afraid of the damage it does at present. Whilst the plantations are young and vigorous this belief may be well founded; but whether it will when the soil gets exhausted, may be problematical.—Your obedient servant,

WM FILLINGHAM PARR.

[Our information as to the virulence of the disease in Fiji was from a trustworthy correspondent. Mr. Parr's friends make light of the fungus. So did Ceylon planters for about five years subsequently to its first appearance in 1869.—ED.]

A MONSTER CINCHONA TREE GIVING 30 lb SHAVINGS.

October 14th, 1882.

DEAR SIR,—Today I have spoke-shaved the largest cinchona succirubra tree in the district. The shavings weighed 30 lb. Who can beat this famous tree of UDAPUSELLAWA?

[In Ambagamuwa and some other districts 40 lb. have been shaved off.—ED.]

CARBOLIC ACID TREATMENT OF COFFEE LEAF FUNGUS IN DIKOYA.

Claverton, Dikoya, 16th Oct. 1882.

DEAR SIR,—There has been so much reference in your columns of late to the carbolic treatment for leaf-disease that I venture to offer a few remarks from my own observations here on Mr. Schrottky's experiments, which are being conducted over a square block of 100 acres. I am not at liberty, as one of the Dikoya Committee, to express any opinion on the results, but this I may say that so far from the carbolic having been *proved* a failure on Claverton (and this is I believe the most essentially test experiment that has yet been attempted) I have been pressed both by members of the Committee and outsiders to continue the experiments for at least three months after the present joint contribution of R3,000, has been expended. This will be from December to April next. Offers of subscription have already been made me, but, as the district has not yet collected its share towards the existing experiment, I feel bound to decline them.

I would suggest your applying to Mr. Schrottky's agents, Messrs. Lewis Brown & Co., for reports on the proceedings up to date, which they will secure in due course, and, if you consider the movement sufficiently deserving of support you might open a subscription towards a fund for conducting the experiments on a more extended scale. I mean by this the carrying out of any suggestions not included in Mr. Schrottky's programme, that might be thought likely to throw further light on the subject: such, for instance, as increasing the strength of the acid on certain portions of the field by way of comparison with others. The reports are at present only open to the subscribers. The treatment commenced in April with Mr. Schrottky's original plan of dusting the trees with a carbolic powder, supplemented by a system of evaporization, which I consider to be an improvement on Mr. Storck's method. So far, and that is from the commencement of the S.W. monsoon, the 100 acres have been singularly free from disease while surrounded by coffee more than usually affected by it. It is still, however, an open question with many whether the good results manifestly obtained are due to the carbolic or to early pruning, and, until the Committee are unanimous on this point, they decline to commit themselves to any public expression of opinion. Moreover, even admitting the success of the treatment so far, it would be impossible to say whether there may not be some fresh phase in the history of leaf-disease, such as a general attack in dry weather, with which the carbolic may be unable to battle.

With regard to the comparative merits of Mr. Storck's and Schrottky's methods of evaporization, I find that the powder used by Mr. Schrottky has this advantage over Mr. Storck's: that it gives off the gases evenly, while it appears to me that, in the water combination, it does not give them off at all, the acid lying at the bottom of the water. Mr. Schrottky's method is open to the objection that the cost and carriage of a powder prepared in Colombo to the estate is expensive, while the acid must lose some of its strength by storage. To those who are now experimenting I would suggest putting out the pure acid in tins or coconut shells containing say 4 oz. river sand to ½ an oz. of the acid. I am inclined to think that this will be found sufficiently porous in itself to give off the gases without any occasion to stir the mixture up during the intervals of replenishing.—Yours truly,

E. H. SKRINE.

WHAT AILS OUR COFFEE TREES?—No. 7

SIR,—It would have been better if I had pointed out in my last letter the wide difference between the *external* attack of a fungus such as hemileia, and the *internal* operation of one like the potato blight. The difference cannot be overestimated. It is as great as that between a cut finger, or a bruised shin, and an ossifying heart, or a softening brain! Mark the difference as it is shown by a comparison of the case of the coffee tree with that of the potato plant! The hemileia affects none of the *permanent* structures of the coffee tree, but is confined entirely to the leaves, which are at most but *temporary* members. On the other hand, the peronospora attcks the vital organs of the potato plant, permeates its whole fabric, and destroys root, branch and tuber! The worst possible attacks of hemileia, when the affected leaves have been cast off, leave the trees absolutely free from disease, with all their essential, permanent organs intact and vigorous,—and the fruit they bear continues to be the very finest in the market. The peronospora, on the other hand, reduces its victim and all its organism to a "stinking, loathsome mass of corruption." So Sir W. Gregory once described to me a field of blighted potatoes! The utmost physiological effect of hemileia on the coffee tree is to

timulate it to the reproduction of the lost foliage, an effort the strain of which is easily estimated, and in fact is well-known. On the other hand, the mildest attack of the peronospora inflicts a *mortal* blow.

He who "propounded the internal ulcer theory" was no "quack" (*Observer* Oct. 14th), but the late lamented Dr. Thwaites,* who, if he ever *entirely* renounced his first formed *opinion* as to the internal character of the attack of hemileia, did so only when the *fact* of its true nature had been established by the exhaustive demonstrations of Mr. Ward. If I am not mistaken, Mr. Abbay also held the opinion that hemileia carried on its operations in the vitals of the tree, and I believe this was assumed to be the case by scientific men at the time the fungus received its name of vastatrix. The terrible ravages of the potato blight were uppermost in the minds of experts at home. So long as the new invader of our coffee plantations was supposed to be of the same nature as the peronospora the alarm it excited was reasonable, and in fact unavoidable, but the old *opinions* have been utterly exploded by the more recently discovered *facts*, and there is no longer the same ground for the terror first inspired. The past history of the coffee fungus proves how very unreliable are *opinions*, even of the highest authorities in such matters; and also how unsafe it is to draw conclusions except on *facts* well ascertained and established. Hence the evidence advanced throughout this series of letters has been adduced entirely from the facts of our experience; and the aid the writer has sought from fellow-planters was from such facts, corroborative or otherwise, as their experience might supply.

To revert once more to the action of hemileia, occasional allusions occur in correspondence on this subject, which are evidently based on a supposition that some hidden mischief is done to the permanent structures of our coffee trees by the action of the fungus on the leaves, as though some poisonous influence were disseminated by means of *circulation*. Indeed, planters frequently speak about *circulation* as if it were an acknowledged fact of vegetable physiology. It may not be altogether superfluous, therefore, to state that such is not the case. There is, of course, a *flow* of sap from the roots upwards, and so long as the idea was entertained that hemileia entered the plant through its roots, and permeated its internal structures in the manner of perenospora, (as some planters even yet believe) the flow of sap gave a sort of sanction to the expression. It is altogether incorrect, however, and therefore any inferences which imply the existence of *circulation* in the coffee tree are inadmissible.

The conditions of fertility in fruit-bearing trees are very obscure. The imagination could scarcely invent theories more curious, fanciful, and apparently inconsistent than the facts of our experience in regard to fruit trees. We see trees which once bore abundantly cease, or nearly cease to bear at all, for considerable periods, without any assignable cause. And we see their fertility restored and perpetuated by the most improbable means. For instance, a pear tree of remarkably luxuriant growth, and renowned in its neighbourhood for its luscious fruit, became utterly sterile for several years, in spite of various remedial measures, and so continued until the desperate expedient of sawing off its largest root was adopted. It then fruited freely for some years. Walnut trees are said to require *thrashing* to make them yield their fruit. Loquats and several other trees, on refusing to bear fruit, may often be induced to bear by a massacre of their largest branches, or a barbarous hacking of their trunks. Vines often remain unproductive till their roots are bared, and the plants receive a check of growth, or an artificial winter, as it is called.—If it were safe to generalize on such data as these, it would seem as if luxuriance of growth, or growth unchecked, were adverse to fruit-bearing. Even in sugarcane, continuous growth in a forcing climate seems to hinder the elaboration of sugar. Two planters from Mauritius exclaimed, on seeing the magnificent canes at Mattagoda, that "*this was the country for sugar.*" But when they saw the liquor in the boiling house, and how the saccharometer stood, they speedily changed their note! We often had to consume the whole of our megass, and sometimes required firewood besides, to get the sugar! We managed to make all ends meet as long as we could obtain retail price for our sugar, locally, but were unable to compete in the markets of the world with the produce of other countries. Eventually, the estate was sold to a Frenchman, who would not be convinced that such luxuriant growth of cane could be so unproductive of sugar. His confident opinion outweighed the facts of our experience, and he spent £12,000 in undeceiving himself. Pardon this digression. It may possibly save some victim from following our worthy Governor's recent recommendation to try sugar-growing again.

Turning again to the subject of continuous or unchecked growth as a condition adverse, in some cases at least, to fruit-bearing, the fact that many of the fruit trees of temperate climates grow profusely in the tropics and yet refuse to bear fruit there has led to the general belief that the check of their wintering in their own countries is what constitutes the difference. And this idea receives some confirmation from the success of such treatment as exposure of roots, and those other means above specified for checking growth. Moreover, our own coffee trees offer some evidence in support of the idea; for we know that the hot, parching weather we usually have in the months of January and February, and the pruning of the trees which usually precedes or accompanies it, have a decided tendency to check growth, and they are also the conditions most favourable to our crop prospects. On the other hand, when these months are wet and forcing, and when growth is unchecked, the formation of blossom is discouraged, and in planters' parlance the blossom "turns to leaf."

The facts of our observation and the results of our experience show that temporary sterility in fruit trees is no rare phenomenon, and though science has not yet probed deep enough into the mystery, we have *facts* to aid our reasoning and research, without resorting to assumptions and theories opposed at once to science and logic.

Other tropical countries have been subject in years gone by to waves of agricultural depression, similar to that through which we are now unhappily passing, and of even longer duration. Some, indeed, have shared with us the ill-fortune of this past decade, and their experience, past and present, might serve to enlighten, and possibly to help us. The ebbs and flows of agricultural tides in other countries offer a promising field for inquiry in our present difficulties. The Board of Agriculture of the U. S. of America, in their annual report for, I think 1879, refer to the persistent failure of the fruit crops of the States for so many years that those crops had ceased to attract attention. And they conclude by a supposition that the "art of fruit culture had been lost." The truth is, not that they had *lost*, but that they had *never possessed* a knowledge of the essential conditions of fertility in their fruit trees! The fruit had come forth abundantly, they knew not why; and it had ceased for reasons they therefore could not divine! If they had had a scapegoat fungus handy, they would probably have been

* Dr. Thwaites propounded what Hooker described as an unscientific theory; but it was not he but an unmitigated quack who wrote of "internal ulcers" developing into *h. vastatrix*.—ED.

content to father their misfortunes on it, and ask no further question; but there was no hemileia there, and they had therefore to confess their ignorance. *We* seem very unwilling to make so humiliating an admission, and some of us prefer to assign a reason which is both insufficient and inapplicable, rather than grapple with the difficulty and obscurity of the question.

W.

WHAT AILS OUR COFFEE TREES?—No. 8.

Sir,—The precise meaning attached to the word *growth* in my letter No. 6, quoted by "Botanist," is shown by the context to be the period of *life-changes*, or that period during which the leaf exercises its proper functions, whatever they may be. This period does not quite coincide with the time the leaf retains its place on the tree, as it often clings there for a considerable time afterwards, till it is displaced by wind or other causes. The measure of loss or injury inflicted on the tree by *hemileia* must surely be limited to, and indicated by the diminution of the term of leaf *work*. In former letters it is admitted that a certain amount of loss accrues. In the latter ones it is contended that the loss is greatly overrated by those who believe the fungus to be an adequate cause of our diminished crops.

The object of these letters has throughout been practical, and the arguments relied upon have been drawn from the facts of our knowledge, independently of scientific theories, whether of leaf function, or of circulation, so-called. The latter theory was incidentally mentioned in No. 7. not by way of argument, but to meet certain ideas I have heard suggested. That subject would have been better omitted, as it involves points that are debatable, and it does not any way affect the facts of the case. Setting aside all physiological theories whatever, we have before us the broad fact of vigorous growth, and in many instances, of a high degree of fruitfulness also, following the most virulent and repeated attacks of the fungus.

Briefly recapitulated, the evidence afforded by the coffee trees themselves of the extent of the injury they sustain after *hemileia* has done its worst, is set forth by (*firstly*) the luxuriant flushes of foliage the trees put out; *secondly* the attainment of full size, firm, healthy texture, bright colour, and all visible signs of mature growth by the individual leaves of those flushes; *thirdly*, the fruit produced being of fine quality, and still maintaining its superiority in the market over coffee of other countries where no hemileia exists; and *fourthly* individual trees and groups of trees, and even whole fields and estates producing heavy crops in spite of the fungus. Such divested of all theoretical questions, are the practical facts, of which every planter may judge for himself. And, if recent accounts from Fiji may be credited, the hemileia in that country has not impaired the fruit bearing powers of the coffee trees to any such serious extent as ours are suffering.

Whatever hemileia may have done to our trees, it has, happily for us, left them still full of vigorous life and growth. They have not been swept off like the nutmeg trees in Penang. Experience shows us moreover that loss of fruit-bearing power is not always a proof of impoverishment. Other causes are, at least, *possible*. What I urge is that they should be *sought*, and if I have been betrayed into too great insistance, I can only plead the deep feeling which the importance of the subject has inspired, and crave indulgence.

Finally, I am persuaded that our hope of success is in the more diligent search and more careful collation of *facts*, as furnished not only by our own smitten enterprise, but by the tides of agriculture in other tropical countries.

W.

GUM LEAF DISEASE.

Upper Abbotsford, Lindula, 18th Oct. 1882.

Dear Sir,—I had one of the shrewdest and most scientific men of the district with me yesterday, and he was perfectly horrified at the gum-disease, of which he says no one who has not seen its effects can have any conception. He puts down my deaths of gums at 90%, but that is a circumstance he rejoices over, considering the havoc they have wrought among the other and more important cultivations, especially cinchona. Tomorrow I have to put on men to cut down pretty well all my young cinchonas, than which, till this disease attacked them, there could not have been a more cheering sight for vigorous and healthy growth. I was told that I was incurring a heavy responsibility by not making the matter more widely known, but I protest that I have from the first wearied your readers with my mention of the subject.

Mr. Marshall Ward's exceedingly clever and profound remark, when specimens were sent to him, will show the encouragement there is to ask the attention of our scientists to this new blight to our industries. Mr. Ward's oracular words were (see *Tropical Agriculturist*. Vol. I. p. 462) :—"Why does your correspondent dignify the spotting (which is a common enough phenomenon, and which I have long observed on many plants) with the name of leaf-disease?" And yet Mr. Ward may be astonished to hear that this gum *leaf-disease* is now considered by those who have seen it to be infinitely worse than the coffee leaf disease over which the Government and he thought it worth while to spend years of thought, labour and money. I have just received a letter from an estate 1000 ft. lower than this, and I found enclosed for my opinion three gum leaves. I could only reply that the disease was there, so I warn my brother-planters that the disease is spreading. I cannot again be blamed for concealing the disease.—Yours faithfully,

A. M. FERGUSON, Jr.

[We have written to Government submitting whether Dr. Trimen or Mr. Nock should not be deputed to investigate and report on this new and fatal leaf-disease, more formidable than the coffee fungus, in some respects, inasmuch as it not only kills the gums on which it first appears, but spreads from them to cinchonas, tea, &c. We have, with many a pang of regret, ordered the eradication on Abbotsford, of the thousands of gum trees which have cost so much trouble and money, but we do not like personally to take the responsibility of advising all other planters to follow our example, especially as the blue gums in Nuwara Elliya and to the eastward of that station are said to be exempt from the mysterious and deadly disease, which cannot as yet be traced to either insect or fungic origin.—Ed.]

"AND TEA AND CINCHONA REIGNED IN ITS STEAD."

Dear Sir,—After a month's travelling on horseback in the interior, I have returned to Colombo deeply impressed that ere many years have passed by the above will be the state of Ceylon so far as agriculture by Europeans is concerned. My excursion led me through the districts of Passelawa, Pundaluoya, Dimbula, Lindula, the Agra Patanas, Ramboda, Udapusselawa and Badulla, and it is only fair to say that my impressions have been derived from what I saw in those portions of the island. Having for the most part gone across country by native minor roads and not by public highways, roads leading through the hearts of estates, I was able to note by the way the present condition and working of the estates, and I could not help arriving at the conclusion, that the

dynasty of coffee has passed, or is passing away and another arising in tea and cinchona. Even in those districts on which coffee is still apparently flourishing, such as the Pundaluoya, Dimbula, Agrapatanas, parts of Udapusselawa and Badulla, the planters seem to have taken the alarm, and to be preparing themselves for the change which is impending, for it would not be possible to name any estate on which the two products of tea and cinchona are not being introduced. In the higher elevations, tea and officinalis seem to be the favourites, while succirubra, called affectionately by the planters, "Succy," enlivens the borders of the roads on the lower estates, or peers above the coffee in the bad patches, of which there are far too many. The bright red and green leaves of this hardy variety of cinchona helps to give a cheerful aspect to the country, and seems to possess the confidence of planters over the more valuable descriptions, such as officinalis, ledgeriana, calisaya and hybrids. Judging by what I saw, the better kinds are used in high elevations, while succirubra and strong hybrids are in favour in the hotter and lower districts. As I said before there are signs of a great change coming over us, and I look upon King Coffee as doomed in the course of time to resign his sceptre to the invading new products which are gradually overrunning the country. And most fortunate it is for owners and mortgagees that something has been found which will grow in apparently worn-out estates. The hardy succirubra, plants itself from wind blown seed, and seems to thrive in the most barren looking soil. I say nothing about cocoa, for I saw none in the districts I visited, but I understand its cultivation is rapidly progressing in districts favourable to its growth.

In speaking of the decline of Coffee Cultivation, I am still of opinion that there are some favored portions of the island where it will prove remunerative for some years to come, especially if home prices improve, or if the present value of the colory coffee be maintained.

On the other hand, I look upon many districts as quite worn-out. Notably those of Pusellawa and Rambodde as far as Nuwera Eliya, and it struck me forcibly that this was owing more to the loss of soil from the system of weeding, than from leaf-disease. It is melancholy to see the once fertile fields of the Pussellawa and Rambodde ranges so utterly desolate as they are at present, so irremediably exhausted, the soil having been washed into the valleys and carried down by the rivers into the sea; draining may have arrested the mischief for some time, but the obligation of cleaning the drains when full of washed down soil, and casting it forth below to be caught in the next drains must necessarily end in its being lost altogether. Such has been the fate of the once famous districts of Pussellawa and Rambodda which I have known since the year 1848, when old Archdeacon Glennie and the Messrs. Worms were living and creating the once magnificent properties of Rothschild and Delta, the glories of which have departed never to return as coffee estates. Both of these large properties are, I believe, now being converted into cinchona plantations.

In endeavouring to account for the extinction of coffee in Pussellawa and Rambodda, I am inclined to believe that the estates have arrived at the natural term of their existence, their lives having been considerably shortened by leaf-disease, but chiefly by the loss of soil under the system of weeding which was perhaps unavoidable.

As to cinchona, I much fear that the necessity of planters is causing them to shave stems and to lop branches, at too early an age; no tree should be so operated upon before it is 4 years old. The operation of lopping is performed also to an excess which is evidently injurious to the tree and undoubtedly checks its growth by depriving it of a portion of its respiratory organs; I may be wrong, but such is my belief from actual observation.

I am glad to say that I noticed very little leaf-disease during my travels except on some estates an accumulation of dead and fallen leaves and I certainly attribute the fearful shortness of crop in the coming season, to exceptionally unfavorable weather during the blossoming season. In this belief the universal cry of the planters is, let us try one more year before abandoning our hope in coffee. When speaking of the cessation of coffee cultivation in Pussellawa and Rambode, I ought perhaps to have mentioned that there are a few estates that are still carefully cultivated, but as far as personal observation goes I only know of three, two in Pussellawa and one in Rambodde. A kind of cultivation is kept up upon some others, but more for the benefit of cinchona than coffee.

Referring to my remarks upon the loss of soil by the system of weeding practised in Ceylon, they are singularly confirmed in an article on cacao cultivation, in the *Planters' Gazette* on the 2nd October.—
Yours faithfully, G.

THE GRAFTING OF LEDGERIANAS ON SUCCIRUBRA STOCKS: BAMBOO CYLINDERS AND BOTTOMLESS BOTTLES.

DEAR SIR,—I notice in your issue of 13th ultimo a letter from Mr. Kemp, giving his experience and method of grafting C. Ledgeriana on succirubra stocks as practised by him at Hope, "Ouchterlony Valley." The letter is very interesting inasmuch as it represents the process as simple and the result a perfect success. Interesting as the letter is, it would have been considerably more so had Mr. Kemp stated what percentage of the grafts succeeded, *i. e.*, in the open, under bamboo cylinders and bottomless bottles also in glass structures. Without this information the letter may mislead, and in the end prove only a delusion. A few words from Mr. Grant, under whose instructions, I believe, Mr. Kemp was acting, would also be of interest—particularly, if he can endorse Mr. Kemp's success as described in his letter under review.

There is no novelty in breaking a bottle by means of oil and a heated rod of iron; this is familiar to every boy in the Madras Presidency. The bottom portion of a bottle so treated being often used in planters' bungalows as a night-lamp before lamps and finger-glasses were so plentiful and common as at present, and I think it would be an easy matter to prove, that the use of the top portion as described by Mr. Kemp, did not emanate from that gentleman. This applies with equal force to the introduction of bamboo cylinders. LEDGERIANA.

Southern India.

COFFEE AND GOOSEBERRY BUSHES.

21st Oct. 1882.

SIR,—Can "W" cite instances where orchards or say large gooseberry gardens—and the appearance and cultivation of this shrub in many respects resemble the coffee tree, after having for a series of years remained unproductive revive and give their previous yield of crop? I knew in Scotland of a large gooseberry garden, of some acres, collapsing in the way our plantations here have done and the owner after years of patience having to root out. L.

PROBABLE ANALOGY BETWEEN HEMILEIA VASTATRIX AND PERONOSPERA INFESTANS.

LINDULA, 24th Oct., 1882.

DEAR SIR,—The great want of rootlets to our coffee trees has been one of the mysterious accom-

paniments of leaf-disease, and has attracted the attention of most planters. The prevalence of grub in the younger districts has been generally assigned as the cause, but it was unaccountable in the older districts where grub does not exist to any considerable extent, unless it were in some mysterious way connected with leaf-disease, the re-action after a bad attack, or the unhealthy condition of the trees caused by hemileia. But none of them appear to me to satisfac orily clear up the mystery. I have been much interested in the letters of your correspondent "W.," and while agreeing with him in the conclusion he arrives at in the last paragraph of his letter No. 7, wherein he attributes the falling-off of the bearing of our trees to a cycle of unfertile years, I must join issue with him in his attempt to draw a wide distinction between the nature of the coffee leaf fungus and that of the potato "peronospera." He says the difference cannot be over-estimated. I would, however, draw his attention to a pamphlet by J. L. Jensen, Director of the Bureau Ceres, Copenhagen, the name of which is "How to overcome the potato disease," published by Menzies & Co., Edinburgh, (an extract from which I herewith enclose) a careful perusal of which, will I think, on the contrary shew that the *similarity* cannot be over-estimated, and mayhap throw an important light on the question of the dearth of feeding rootlets. You will see that the exhaustive experiments of Mons. Jensen leave no room to doubt that if the spores of the peronospera which fall from the foliage, can be prevented from being carried by rain water into direct contact with the tuber, the potato does not become infected, even although the foliage may be entirely destroyed. It is now some forty years since the potato disease was first discovered, and hitherto it has been understood that either the foliage was first attacked and the disease conveyed by the stem to the tuber, or *vice versa*; this too, notwithstanding that the science of every civilized nation has been brought to bear on the subject, studying its life history and devising remedies, as we know, to little or no purpose. It has been reserved for the scientific and practical Mons. Jensen to discover the real working of the pest and a simple and economical remedy. In the face of the foregoing, then, may not Marshall Ward's "Life History of Hemileia Vastatrix" be to some extent inaccurate? Is it not possible, nay I think extremely probable, that the spores of the fungus may be carried to the young and tender rootlets, entirely destroying those they come in contact with? Marshall Ward found no traces in the stem or roots, which may be easily enough explained by the fact of the germinal tube of the spore being unable to penetrate the more tough epidermis of the stem and root. It must be remembered that the spores do germinate on the ground under favourable conditions, and the very tender rootlet may become their temporary host, the destruction of which would be a matter of very short time. If the potato fungus finds an equally genial host in the foliage and tuber of the potato, why should not hemileia devastate both leaf and rootlet. I have always held that our coffee suffers more from want of rootlets than from the fall of leaf. Should it therefore be found that there is truth in my conclusions the combatting of our common enemy will be much simplified. It has occurred to me further that the extraordinary increase of the grub pest may be entirely owing to the rotting rootlets being a favorite source of food for the grub. I can from actual observation vouch for the fact that grub feeds greedily on decaying rootlets. At all events, the whole subject is well worthy of further investigation by planters, as well as by local experts.—Yours faithfully, J. S.

[We have already given several extracts bearing on Mr. Jensen's method in the *Tropical Ayriculturist*. The following is the essential portion of his paper.—ED]

The vital point in the system, as it will be noticed is the "Protective Moulding."—In order to understand the effect of this, it will be necessary here to add a few words about the cause of the disease.

The disease is solely due to the attack of a parasitic fungus, Peronospora (Phytophtora) infestans. When the summer has somewhat advanced this fungus produces the well-known dark-brown spots on the foliage of the potato, where it develops its "seeds," the so-called spores. The fungus-seeds are often so numerous that a single plant, according to countings and computations, successively can bear 20 to 30 millions of spores. Falling to the ground, these spores are carried down with rain-water to the tubers, upon the surface of which they germinate. The sprout-fibres penetrate the skin of the potato-tubers, and develop under the skin a dense tissue, the so-called mycelium. As a consequence of this, the potato is, "sick," *i.e.*, covered with brown spots (and at last becomes smuttish-brown upon the entire surface), has a bad taste, and is in process of rotting.

Luckily the soil has the property of impeding to a great extent the progress of the spores, operating as a filter. The object to be sought, then, is to throw up upon the tubers a covering of earth of sufficient thickness to prevent the spores from filtering, or only allowing an insignificant minority to filter through to reach the tubers. By means of systematic experiments in the open field, and several series of corresponding investigations in the laboratory, I have shown, that, when a 5 inch layer of earth is hoed up upon the uppermost tubers, only very few will become diseased, be the attack ever so violent. Such a layer of earth is, therefore, the principal thing in the protective moulding. The drawing over of the potato tops to one side of the drills, the second point in the perfect protective moulding, is, in comparison with the thick covering of earth, of a subordinary, but, nevertheless, by no means un-essential importance. The object of the bending over of the tops is to prevent the rainwater from trickling down the vine into the ground, whereby they would find a less obstructive way to the tubers. When furthermore, the tops hang out over the adjoining furrow, fewer spores will fall upon the ground directly above the tubers than if the stalks stood erect.

'W. D. B." ON "W.'S" LETTERS

AND ON THE COMBINED INFLUENCE OF LEAF-DISEASE AND METEOROLOGICAL CONDITIONS ON COFFEE CROPS.

October 24th, 1882.

DEAR SIR,—"W.'s" letters are apparently written to prove that neither leaf-disease nor unfavourable seasons are the cause of our present infertility. Few people are there who lay the blame on either one without the other, but to most the combination of the two is sufficient to account for the present year of disaster. In attributing the present infertility mainly to season, I am not one of those who would leave out of account the "fatal fungus," but, as in spite of it we still see estates bearing comparatively well when favoured by season, I have laid the chief weight upon "climate influences." I maintain that "W.'s" arguments are in favour of my theory, as in the letter of your issue of 19th instant, where he says that the hot parching weather usually experienced in January and February, gives the trees a check in growth. This check is necessary to the production of crop, as I will endeavour to show.

I am aware that my theory runs counter to that of the new school of botanists, who look upon all flowers as aborted leaves, and which it appears to me, therefore, reduce the question of reproduction to a combination of apparently accidental conditions, or conditions which they are unable to reduce to law. As a strong upholder of the necessity of maintaining the highest conditions of fertility in the soil and plant for the production of the best crops, I cannot

admit their view of the question. As far as the coffee tree is concerned, its life appears to me to be divided annually into two parts :—1st, that of growth which commences with the first monsoon rains and ends when the season for blossoming begins, during the 8 or 9 months of which the plant is gathering and storing material for the second period : that of blossoming. On the Uva side of the country, the same holding good to a modified extent. Now, as "W." says, the effect of the dry weather usually experienced at this second period is to cause a check, which check, I contend, is necessary, not in order to produce aborted leaves in which light the blossom is by some regarded, but that by causing greater local concentration, the tree may be enabled to put forth its highest powers towards reproduction. The process being similar to that of the concentration of salts in solution by evaporation. This theory appears to me easy of comprehension and a reasonable explanation of the effects of a normal season and artificial checking, which, bearing out the system I uphold of early pruning and manuring with a view to giving the tree as much time as possible for storage of food ; by late manuring or oversupply of nitrogen, the season of growth being artificially prolonged. So much for the argument as regards the influence of season.

With respect to the "fatal fungus," the effect it has as compared with "wind" in causing loss of leaf, is different as regards the resulting crop, and the explanation may lie in the following suggestion, viz., that the disease feeds on the food contents of the leaf, to supply which exhaustion the leaf draws upon the branch, and, thereafter, falling-off, leaves the branch destitute of sufficient material for the formation of crop, while the wind has rather the effect of driving back the sap into the branch and causing the desired local concentration, so that the green part of the branch is still capable of performing the function of the leaf after the latter has been lost, as far as the requirements of the blossom are concerned.

However far "W." is correct in saying that the falling-off of crops in the last decade is not commensurate with the attacks of leaf-disease, it is evident to most planters that, the time of an attack is of most material importance, and, if, as was the case this year in Matale and other districts, an unusually severe burst of leaf-disease lays the trees bare in January, the result in short crop is inevitable, unless the fine season is sufficiently prolonged to enable the trees once more to clothe themselves with mature foliage.

Given but a mild attack of leaf-disease and a dry blossoming season in the early months of the coming year, it needs but little of the gifts of prophecy to predict a good crop for 1883-84 on the estates which "W." says are now looking so luxuriantly healthy.—Yours faithfully, W. D. B.

LANTANA PLANT.

DEAR SIR,—I have heard of another name (not a lady's) connected with the history of this plant in Ceylon. Originally a native of Brazil, it is said to have been brought here some forty* years ago from Mauritius by Sir Hudson Lowe, then commanding the forces in Ceylon. We are inclined to believe, too that, in the case of this plant, the evil it occasions is not wholly unmixed with a share of good effect. It is believed by some capable of forming a competent judgment that, by choking down all other growths, by forming an impervious covering to the soil, and by appropriating and bringing up to the surface deep-lying mineral elements, which, on cutting down and burning the plant, are restored to the soil as ashes, the lantana is calculated to improve the fertility of the soil and to restore it where exhausted.

In its native country, as also in Mauritius, and where it has been grown in India as a garden plant, it has not shown any special tendency to spread, but in Ceylon its career has been altogether different. Brought here as an interesting shrub forty [sixty] years ago, planted as a garden flower thirty years ago,* it has since that time spread as an uncontrollable weed through a great part of the length and breadth of the island. Everywhere are to be seen its thick half-bushy, half-climbing growth, its pungently smelling foliage, its bright orange-red flower. It lines the sides of roads, spreads over pattana and chena ground, rapidly covers abandoned coffee ground where the altitude is not too great, grows along the banks of paddyfields where its seeds have been drifted by streams or conveyed by birds, and is also seen making successful war with the natural jungle, choking down the creepers and smaller bushes, and even over-growing and smothering the young forest trees, thus tending to effect a change in the character of large tracts of vegetation, a change of which it is scarcely possible at present to estimate the ultimate result. A recent writer says :—"Similar instances of the rapid spread, on being taken to a congenial soil and climate, of plants which in their native homes are of an unassuming, unaggressive character are not wanting. The degree to which English rivers have been choked up by the growth of an American waterweed, the *Anacharis alsinastrum*, and Australian rivers by the familiar English watercress, is an example in kind, while a more extensive one is afforded by the immense spread of the Scotch thistle on the plains of Australia and the Pampas of South America. Readers of Sir Francis Head will not forget the gigantic thistles through which he passed in his memorable 'gallops across the Pampas, and in Australia, where the thistle was introduced a few years ago by an over-patriotic Scotchman, who loved the emblem of his country, not wisely but a great deal too well, the thistle has taken possession of enormous tracks of pastoral lands, and costs the colonies many thousands of pounds annually to keep it from covering the greater part of the country."

TRAVELLER.

* More than fifty. We have heard the introduction of the plant attributed to Lady Brownrigg who left Ceylon some sixty years ago at least.—ED.

SUGAR IN QUEENSLAND.—Very bad news reaches us from the Clarence River, where the frost has been very destructive among the cane fields.—*Planter and Farmer.*

TEA.—The latest reports from the agents of the Calcutta Tea Syndicate in Australia and America give a very favourable account of the prospects of the Indian trade. A great demand has latterly sprung up in New York for the finer teas, as well as for the commoner black kinds that have been chiefly sold hitherto. In Melbourne the cry is for smaller chests to suit the requirements of the store-keepers, It is important that this should be appreciated by the planters, and the tea made up in smaller packages at the gardens, repacking at Calcutta injures the quality, and the Australians themselves entertain a prejudice, no doubt well founded, against tea that has been meddled with in the colonies. It appears that the demand at Melbourne last August actually outran the supply, and for some time there was no Indian tea to be had at all, in consequence of which several traders gave up the Indian business altogether. The fact only shows how much care is required in the management of a new market.—*Pioneer.*

* For more than thirty years it has been a common jungle plant.—ED.

THINNING PEACHES.

The *American Agriculturist* has the following:—"The Hon. A. S. Dyckman, of South Haven, Mich., is a noted grower of fine peaches. One of the leading points in the management of his orchard is that of liberally thinning the young fruit. In 1877 from one Early Crawford tree, set 17 years, he thinned at one time 8,000 peaches, and at another 2,000, making 10,000 in all, from a tree which finally yielded about 15 baskets of choice fruit. One man would spend a day in thinning four to six trees. The cost of thinning peaches does not exceed five cents a basket for those ripened. He estimates the cost of thinning his peach crop in 1877 at $500. Peaches were plenty that year, but he received extra prices for fine, large fruit, which had little competition. He has practised thinning for several years, and is assured that the excellent reputation which his fruit enjoys is due to this. In pruning, he removes one-third of the small limbs. He then removes nine-tenths of the young peaches, leaving no two nearer than six inches of each other. He has fewer specimens to handle, but about as many bushels as though he had not thinned. We have similar testimony from J. J. Thomas, E. Moody, President Wilder, and others, as to the utility of thinning apples, pears, &c., as well as peaches. Mr. Geo. Parmelee, of Grand Traverse County, says that in one year peaches on a thinned tree brought $2.50 per basket, while the fruit from a neighbouring tree of the same variety, but unthinned, brought him only $1.25 per basket. It pays to thin fruit when young. It costs less than one would suppose until he tries it. No one who has fairly tried the experiment, and seen the result, will abandon the practice."

CARBOLIC ACID *VERSUS* INSECTS.

BY PROF. A. J. COOK, MICHIGAN AGRICULTURAL COLLEGE.

Few insect pests are more annoying to the gardener than the Radish Fly (*Anthomyia raphani*), and the Squash Moth (*Ægeria cucurbitæ*). This has been the more true as the remedies heretofore offered have not been satisfactory. The hot water remedy suggested by the late Dr. B. D. Walsh, perhaps the best, proved too inefficient to make it desirable for general use. These enemies are becoming widespread in our country, and a sure preventive of their mischief is greatly to be desired.

For the past two years I have been experimenting with Bisulphide of Carbon to destroy subterranean insects. This substance has proved effectual, but in case of the insects in question, especially the Radish Fly, its expense is an objection to its use. The past season I have tried a new remedy with gratifying success. This consists of a preparation of Carbolic Acid. The material which I used was prepared as follows:—Two quarts of common soft soap was added to one gallon of water, and all heated until it commenced to boil, when it was removed from the stove, and while yet hot, one pint of crude Carbolic Acid was added, and all thoroughly mixed. This was then set away in a close vessel, and was ready for use as occasion might require. To repel the insects in question, one part of this mixture was added to from 50 to 100 parts of water, and the new mixture was sprinkled on the plants as soon as they were up, and after that once every week. In case of the Squash Ægerian the first application need not be applied earlier then the first of June. The same preparation will serve to repel the Cabbage Fly (*Anthomyia brassicæ*). But for the lattter, my experiments go to show that Bisulphide of Carbon is cheap, efficient, and does not simply drive the fly away, but destroys the maggot. As "he that fights and runs away, may live to fight another day," the Bisulphide of Carbon remedy is, I think, to be preferred to the Carbolic Acid mixture for use against the cabbage maggot. We sprinkled the Carbolic Acid preparation directly upon the radish plants, without injury to the latter, but if it is found to injure the plants, from too great strength, it will serve as well to turn it in a trench made close along beside the rows of plants. The peculiar odor of the acid which repels the flies as they come to deposit their eggs, so far escapes, that it is necessary to apply the liquid as often as once a week to insure perfect success. Caution is required also that the preparation is not so strong as to injure the plants when placed immediately upon them. From one season's trial I can strongly recommend the above application.

Though not pertinent to the question now under discussion, it may not be amiss to state that some of our most able fruit growers think that the best way to fight pear blight is to cut away affected branches as fast as they appear, and dip the cut end of the branch in Carbolic Acid. Prof. W. W. Tracy, Superintendent of D. M. Ferry's Experimental Garden, thinks he once cured an orchard of blight in this way. Surely if this evil is of fungus origin, as Prof. T. J Burrill thinks he has demonstrated to be the case, this view would seem reasonable.—*American Agriculturist.*

FACTS ABOUT FODDER: GRASS GROWING.

One of the results of investigation at Rothamsted is to sweep away an authority that may yet attach itself to the once famous "Mineral Theory" of Liebig—that to maintain fertility in the soil, it is necessary to return to it periodically all the mineral or ash constituents of the plant, in quantities proportionate to the amount removed by the crop, and that when this is done, the vegetation will collect for itself ample nitrogen to meet its requirements. In common with the arable crops, from which Messrs. Lawes and Gilbert drew the arguments for their memorable controversy with Liebig five-and-thirty years ago, these plots of permauent pasture exemplify the advantage of adding nitrogen artificially. In addition, they show that the amount and nature of the mineral matter that must be returned as manure will be determined, not so much by what is taken away in the crops, as by the relation of the store in the soil to the requirements of the crop to come. Besides, at the worst, the real measure of loss to the soil is not what is removed by the crops, but what is sold off the farm. Neither would it be as necessary to put as much manure on rich deep loams as on light porous sandy soil, which suffers a greater loss by drainage. M. Georges Ville, in his work on "Artificial Manures," condenses his ideas on this subject into the aphorism, "Give back to the land more phosphoric acid, more potash, more lime, and half the nitrogen taken away."

The following table sums up some of the chief botanical facts that have been indicated with regard to the Rothamsted experimental meadow.

The figures indicate the number of species represented and their proportional percentage by weight of the whole crop.

Treatment of Plot.	Species of Plants.			
	Grasses.	Leguminosæ.	Miscellaneous Herbage.	Total Species.
Without manure...	17 species=68 per cent.	4 species=9 per cent	28 species=23 per ct.	49
Heavily manured, and yielding the heaviest crop.....	12-13 species=95 per cent	1 or 0=·01 per cent.	5-6 species=5 per cent.	19
Dressed with manure best suited to beans and clover.....	17 species=65·7 per ct.	4 species=20 per ct.	22 species=15 per cent.	43

Bearing in mind that when these experiments were first commenced a uniform herbage covered the whole seven acres, and that no new seed has been sown for at least half a century, the great variety of herbage appearing in contiguous plots presents a very interesting example of the "survival of the fittest."

The discussion of the individual characteristics in the different fodder plants found in meadows is manifestly too detailed a matter to be treated on in an article confining itself to general principles. Moreover, the subject is complicated by botanical as well as chemical considerations. Besides this, meadow grass is not like a cereal crop, made up of one species, always cut at the same stage of its existence, but is a highly complicated mixture, containing many species in various stages of maturity.

Hence whilst the cereal crop will have a composition that is regulated chiefly by the kind of grain grown, in the meadow grass the nature of the individual grasses sown does not so much affect the composition of the hay as maturity, soil, and season.

It is evident, therefore, that, when laying down permanent pasturage, it will not do to sow all the best seeds, and leave the rest to Providence. One must suit one's seeds to the soil, and the manures to the special kind of grasses one wishes to grow. Even then all the extra trouble is lost if, from want of hands or from the desire to obtain a larger crop, the grass is allowed to get over ripe.—*Field.*

THE TEA INDUSTRY OF JAPAN.

There are features in the tea trade of Japan which are full of interest as commercial facts, as well as having an important bearing on our tea industry. In the first place, tea has been grown and highly cultivated there from time immemorial, although the proper manipulation and export of the prepared leaf is of comparatively modern date, say of the last sixteen years. There are many plantations in the neighbourhood of Yeddo with tea plants on them whose recorded age is three hundred years, and in the garden of the Mikado there is one said to be a thousand years old. This latter is, however, a veritable tree from which the leaf is no longer taken, but the others continue, at their great age, to give steady crops of leaf.

But these harvestings from ancient plants, for plants they continue, are the results of continued high cultivation by means of manure and working of the soil, at which the Japanese are adepts. In Japan, as in China, the tea plant is never grown on steep land as it would then be impossible to manure it sufficiently, and moreover the wash from heavy rains would be detrimental. The Japanese preserve most carefully every particle of vegetable and animal refuse, all night-soil and stable manure, without which it would be impossible to obtain successive crops from the same plants for such long periods. The system of irrigation in Japan is likewise most perfect, and by these united means the land is maintained in constant fertility at all periods of the year, and, as a consequence of the invariably vigorous state of the plants, disease or infertility is unknown amongst them. Notwithstanding this high cultivation, the yield of leaf does not appear to be so large as might have been expected; but it must be remembered that the islands of Japan are situated in north Latitude 30° to 40°, and that the tea districts of Yeddo are situated in about 36° N. Lat. where, during the winter months, the cold is sufficiently great to produce frosts, consequently there can be no flushes from October to March. This is shewn by the fact that there are but three pluckings in each year. The first of these takes place in April, when the youngest and finest leaves are gathered; the second gathering takes place in June, and a third in August. At each of these gatherings the leaves are larger and coarser and are used for the manufacture of a lower grade of tea. We have no data to show the yield of tea land per acre, but with only three pluckings yearly the annual produce can scarcely be so large as that in India, or in our own case, where four hundred pounds weight of dry leaf have been taken in per acre, as on a portion of the Galbodde estate.

The export trade in tea has not declined, and, as for losses having been made, most of the business done is by American houses of agency with America, has been on commission alone, and there is no other export trade. Of the fact of adulteration having been practised of late years by the admixture of leaves of some other plant than tea, there is no doubt; and adulteration which is carried on by the Japanese growers and which may, if not checked, exercise a prejudicial influence on the trade with America. Mr. Sibthorpe, the Calcutta Syndicate's Agent, who lately visited the United States, alludes to the fact of adulteration, as also to what is stated to be indifferent preparation, and he believes that these facts are paving the way to an extensive business in Indian teas for the New York and other markets.

The most interesting fact, however, to which we wish to direct attention in reference to the Japan tea industry, is that, whilst the growth and harvesting of the leaf are entirely in native hands, the final preparation, manufacture, and packing of tea are carried on by European or American experts; moreover, this manufacture is conducted at large central factories in the immediate neighbourhood of Yeddo and Yokohama, fifty or sixty miles distant from the places of growth, a procedure which has been hitherto considered as impracticable by Ceylon growers. It appears that the cultivators give the leaf a partial firing, sufficient to keep it for several months, and in that state, without any further manipulation such as rolling and full firing, the natives of the country have been in the habit of using it. It was only on the settling of American citizens in the country, and the qualities of this imperfectly prepared tea becoming known to them, that a thorough manufacture of the article was taken in hand by them.

The tea finally fired, rolled, and packed, by Americans thoroughly conversant with the trade, very soon attracted attention in the United States, where there is now an annual consumption of about forty millions of pounds, the larger portion of which is green tea. This has been going on for about sixteen years, and there are now a dozen firms at the Japanese ports engaged in the business. These purchase the half fired leaf from middlemen, who collect it in the tea districts, and from this crude material, by judicious and careful treatment, the required grades of tea are produced, and packed in boxes of a light, symmetrical, and convenient make, when they are covered with light matting, and a fancy imprint or label in colors, to catch the eye of the trade purchaser, is fastened over one side. We are assured by a gentleman recently engaged in the Japanese tea trade, that if our tea shippers to the States desire to make any way in that market, they must pay the utmost attention to the "get up" of their packages; the boxes must be light and well-made, uniform in size, and instead of being roughly marked or coarsely labelled as though they were wine or beer cases, they must be neatly covered with something like artistic effect. These remarks entirely agree with what Mr. Sibthorpe has written from New York, and it will be well if Ceylon shippers to that and other markets, bear them in mind. The Japan teas are not likely to make their way in Europe, being far too poor in liquor to suit those markets. The citizens of the States appear to be well pleased with the light-colored, delicate flavored teas sent them from Japan, and it will probably take some time before our stronger flavored teas find much favor in the States; the more necessary therefore will it be that the packages in which the tea is shipped be such as will commend themselves to the eye of public, ever taken by appearances.—"Ceylon Times."

EUCALYPTOGRAPHIA.*

By the publication of another decade of his Eucalyptographia, Baron von Mueller has added a valuable contribution to the botany of Australia. It is well known to the students of the vegetable kingdom that no genus is more perplexing than that of Eucalyptus, and that no systematical arrangement of the species has yet been effected which is not open to objection. A work, therefore, like that of Baron Mueller's, which is recording from all parts of Australia the peculiarities of our Eucalypts, their geographical distribution, their alliances with each other, and the extent of their variation, may be regarded as an instalment towards the solution of a most difficult problem. Of the species indigenous in Australia, the Baron has now furnished descriptions and figures of 80 well-defined forms, some of which have already obtained a local habitation and a name in the third volume of the "Flora Australiensis," whilst others, as will be seen, in the present decade, are new to the scientific world.

(1.) The first species of the present series is *E. cordata*, a shrubby plant from the south-east coasts of Tasmania, ascending to elevations of 1,600 feet above the sea-level. It derives its specific name from its heart-shaped leaves, and resembles E. pulverulenta, or the "Argyle apple," in the southern parts of New South Wales. It differs, however, from that species in being restricted to places near the coast, whilst the size of the tree, as well as the shape of the seed-

* EUCALYPTOGRAPHIA: A descriptive Atlas of the Eucalypts of Australia and the adjoining Islands, by Baron Ferd. von Mueller, K.C.M.G., M. and Ph. D., F.R.S., Government Botanist for the Colony of Victoria. Eighth Decade. Melbourne: John Ferris, &c., 1882.

vessels, seems to indicate a marked distinction. E. cordata was first noticed by Labillardiere, and subsequently by R. Brown.

(2.) *E. erythronema* is a small tree found towards the remotest eastern sources of Swan River, and also near Mount Lindsay. This species, as its name implies, has red filaments, which the Baron thinks may give it a place in ornamental shrubberies; whilst the leaves, which are very full of oil-dots, are likely to be utilised for the purposes of distillation. In reference to E. erythronema the author makes the following interesting remarks: "This is one of the enormous numbers of endemic plants for which the vegetation of extra-tropical Western Australia is so remarkable, the genus Eucalyptus forming there no exception to that rule, inasmuch as out of 36 well-marked extra-tropical species known from there, 29 are not occurring in any other portion of Australia!" The isolated character of certain western genera is a problem yet to be solved, for not only several of the Myrtaceæ are limited to that region, but also the large Proteaceous genus Dryandra.

(3.) *E. gamophylla* is a species from Western Australia, recently described by the Baron. It is not large, but its opposite connate leaves, chalky colouration of the foliage, and narrow membrane of the fertile seeds impart a peculiar character to the plant. The Baron regards the distinctive character of the sterile and fertile seeds as remarkable, because such distinction is noticed in so few Eucalypts. It is stated that the missionaries in Central Australia employ the wood of E. gamophylla for various utensils, as it is easily worked, and few other woods can be obtained in that region.

(4.) *E. macrocarpa* is only a shrubby species, but it is interesting as having orange-coloured or crimson flowers and very large seed-vessels. It seems limited to Western Australia, and occurs on sandy and gravelly soil. The first notice of E. macrocarpa occurs in Sir W. Hooker's "Journal of Botany for 1840;" and the late Mr. James Drummond, the discoverer of it, reported it as having claims for ornamental culture. The accomplished Miss North during her late visit to these colonies prepared an oil-painting of E. macrocarpa for the Art Gallery at Kew.

(5.) *E. preissiana* is another small Eucalypt restricted to south-west Australia, occupying generally stony localities and showing a predilection for the limestone formation. The flowers are somewhat large, usually two or three together, and the filaments pure yellow. The Baron says that this species always retains its bushy habit, and thus may be kept manageable for glasshouses in colder countries, the foliage and particularly the bright yellow filaments rendering it well worthy of a place in ornamental collections. The specimens from which this Eucalypt was first described were procured by Dr. L. Preiss, and hence the specific name.

(6.) *E. pruinosa* is a small tree, frequent in the arid country around the Gulf of Carpentaria. It has opposite leaves and resembles "the silver-leaved iron bark" of the northern parts of New South Wales and Queensland. The two trees are so similar in appearance that Dr. Leichhardt mentions them indiscriminately; and yet the species differ not only in the texture of the bark, but also in the openings of the anther, a technical distinction to which Mr. Bentham attaches much importance.

(7.) *E. pulverulenta* is the only species of the present decade which is common to New South Wales and Victoria. It has a resemblance to the tree popularly termed "apple," and attains a height of 40 or 50 feet. Although, in the minds of the colonists, this seems a well-defined species, yet the Baron regards it as somewhat dubious, being impressed with the idea that it may ultimately prove a variety of E. Stuartiana, or a tree known as the "Camden woolly butt." This is the only Eucalypt in Victoria which has opposite leaves, and hence it has received a full elucidation. It is impossible to say, in the present stage of inquiry, how far a geological formation and hybridization may affect certain Eucalypts, but certainly the two trees appear distinct.

8. *E. pyriformis* belongs to Western and Southern Australia, occurring for the most part in the eastern interior of the former, and north of Fowler's Bay in the latter. Mr. Tietkins, F.R.G.S., the companion of Mr. Giles, collected specimens of this shrub near the Victoria Spring. Though small in size, the flowers and seed-vessels are comparatively large, and the filaments are attractive on account of their crimson colour. The specific name is derived from the pear-shaped calyx. "*E. pyriformis* has claims for ornamental culture, specially where in an arid climate garden-copses are required."

9. *E. santafolia* is a species defined by Baron Mueller, and occurs near King George's Sound, in South Australia, and on Kangaroo Island. It is a mere shrub, restricted to coast regions, and flowering when only a few feet high. Though smaller, this Eucalypt resembles in many respects the stringy bark near Sydney; but the Baron remarks, that, independently of other distinctions, the seedlings of *E. capitella*, transmitted to him by the Rev. Dr. Woolls, are "star-hairy," and produce differently-shaped leaves.

10. *E. sepulcralis*, the last of the decade, is a species recently described by the Baron. It is indigenous in S. W. Australia, and has a habit similar to that of the Weeping Willow. In consequence of this strange-looking or sombre habit, it is named "Sepulcralis," as it may hereafter add "another emblem of sadness to the tree-vegetation of cemeteries in climes similar to ours." In reference to the peculiarities of this species, the Baron remrrks:— "The importance of the form and structure of the anthers for diagnostic purposes was first recognised in the 'Fragm. Phytogr. Aust.,' vol. II., pp. 32 and 70, and these characteristics have been well employed by Bentham for the primary systematic grouping of the Eucalypts. But for methods of arrangement also a carpologic system could readily be elaborated with this advantage, that any species might thus be defined from fruting specimens alone. . . . *E. sepulcralis* furnishes a good instance of the advantage of a system based primarily on fruit characters."

From the above notices it will be seen that the 8th q. decade of the Eucalyptographia opens some very interesting questions for consideration. Some of the smallest of our Eucalypts have the largest flowers and seed-vessels, and other species are extremely local in their character. And then, again, we have species which do not exactly suit the technical classification of the *Flora Australiensis*, which it seems was first suggested by Baron Mueller, and subsequently elaborated by Mr. Bentham. There can be no doubt that the antherеal and cortical systems of grouping are a great improvement on the old method of separating species according to the comparative length of the operculum; but there are difficulties in both systems. It may, therefore, be of great importance to follow up the suggestion of the Baron and initiate "a carpologic arrangement," which would place together in separate groups all the known species according to the configuration of the fruit, the nature of the values, and the peculiarity of the seeds. If, indeed, it is as true in systematic Botany as it is in religion "By their fruits ye shall know them," here we have a national system of classification which may lead to the solution of many difficulties. The figures of the decade, with the sectional drawings, are well executed, and the getting up of the work is highly creditable to the Government Printer of Victoria; whilst the lucid descriptions of the Baron are leading us gradually to the clearing up of the clouds and darkness which have hitherto rested on the genus Eucalyptus. It is a curious fact, that whilst many in the colonies think lightly of the species, and others are doing all they can to destroy them by means of ringbarking, the labours of Baron Mueller are causing their properties to be known throughout the civilized world; and hence, wherever it is practicable, they are being cultivated for medicinal, ornamental, or industrial purposes. These colonies are much indebted to the eminent botanist of Victoria for his exertions in developing their vegetable resources, and he may rest assured that his name will ever be associated with a flora which he has devoted the last years of his life to elucidate.—*Sydney Mail.*

CULTIVATION OF THE WATTLE FOR BARK.

The diffusion by the press of the knowledge that bark has advanced almost to a prohibitive price has naturally incited many to think of undertaking the growing of wattles as a profitable crop. During the last year or two inquiries for wattle seed have been quite a feature of the Melbourne seed trade, and, as was recently mentioned, the supply has been greatly below the demand. Orders have come not only from within the colony, but even more

largely from without. The knowledge that the bark of certain of our wattles is one of the most highly-valued tanning materials has led to considerable areas being sown in Southern Europe, where the climate is adapted for the culture. Some of those sowings having been made as much as 12 years ago, there is, doubtless, now a supply of locally-grown seed, and force is lent to this supposition by the fact of the demand from thence having been almost discontinued during the last few years. New Zealand is growing our best wattle (the golden), and should soon produce more than enough for local wants. Our tanners, however, feel confronted with a difficulty from which they perceive no means of escape. The price of bark has risen, in their opinion, immoderately. It is a fact, however, that although the price has risen so high, it is still procurable in England at not higher rates than oak bark. In our latest files (January 27) from London the bark trade is thus quoted:—Mimosa (wattle) per ton ground, £10 to £13; chopped, £9 to £12 10s.; long, £6 to £10; English oak "per load," £12 to £14. In some parts of England oak bark is sold by the ton, but we have no recent market report in which the word "ton" appears. It is evident, however, from reference to other sources of information, that the price of oak bark is not much, if any, higher than "mimosa ground." Seven years ago best samples were quoted £8 and £9 per ton, and as prices have since advanced considerably, the assumption we are hazarding is probably fully justified. Whether oak bark or mimosa be the higher in value, the fact remains that English tanners can give for our bark prices very much higher than those of which our tanners complain, and from which some of their number would apparently seek relief in a specially objectionable form of legislation. The evidence at present available would appear to show that there is no real scarcity of wattle-bark in this country, but that the localities in which it is growing are so distant from railways or water carriage as to raise prices to the pitch complained of by tanners. It shows also that there are reasonable grounds for believing that the price of bark will not be liable to fall much below its present range. At least three years are required to grow a crop, and that circumstance will always be a bar to the culture by many; the majority look for a quick return; they regard a few months as a long time to wait for returns in a country where business is so active. The suggestion in a recent communication to *The Argus*, "that there is plenty of bark for local requirements, providing it can be kept in the country," is one of the most selfish that could possibly have been made. If adopted, it would totally prevent that extension of enterprise in the way of wattle-growing for the sake of the bark which appears now to be in a fair way of becoming developed. The suggestion Mr. Ferguson has made in reference to the collection of seed is commendable, and if in the pursuance of the system of forest conservation the Government is enabled to foster the growth of wattles, such action will be perfectly legitimate. On the general question whether wattle-growing can be profitably undertaken by private landowners, our own columns have at various times contained evidence that it can be done. Below, we reproduce from *The Australasian* of July 9, 1877, a letter on the subject, showing that bark-growing can be carried on profitably at prices less than half those ruling today. By economising seed in the manner recommended a great stride might be made in the course of the first year towards establishing wattle cultivation upon farms. There must, however, be no legislative movement by the Government in this matter; anything of that kind would only defeat the object in view, viz., the development of wattle culture by occupiers of land.

The following is the letter referred to above, and which appeared in our issue of June 9, 1877:—

TO THE EDITOR OF THE "AUSTRALASIAN."

"SIR,—If you have no objection I will supplement your remarks in answer to your correspondent signing himself 'Wattle Bark.' I think that the time has now come that the cultivation of wattle bark will pay, and pay very handsomely, considering the small amount of labour attached to it, and that it can be combined with grazing, notwithstanding your remark anent stock-proof fences. Light sandy soil, or soil that will turn out potatoes in payable quantities, is the description that the wattle requires. Supposing 'Wattle Bark' to have such a piece of ground, let him either clear it completely of all the trees, or take out all the saplings and a few of the trees where they stand too thick, burning off all the rubbish and dead timber. Then lay out his ground in squares of 12ft. each. This done, let him take every third line, and at the intersections of the cross lines drop two or three seeds. That is all for the first season. The second season he does the same with the next line. The third season he finishes. He can then strip the first season's sowing and sow again. The seeds when planted to be lightly covered, to save them from the birds. As soon as the seedlings are well up, the weakest to be pulled up and thrown away, leaving one as each intersection. After the stripping the stripped trees to be cut down, burnt, and the ashes strewn over the ground. The second year of growth, or sooner if the plant is strong enough, clear off all the superfluous branches, so that the stem will grow up straight and clean, giving more bark, and greatly expediting the stripping. When the seedlings are, say, six months old, stock can be turned in on the grass. As long as there is a good bite of grass, stock will not interfere with wattle, nor, for the matter of that, stock will hardly at any time. The time for sowing should be directly the seed is ripe; they will then catch the first rains. The best kind is the wattle that has a smooth leaden-coloured bark, the tanners liking it best, as it contains the most tannin, gives the greatest weight per acre, and commands the highest price in the market. A tree three years old will give half a hundredweight at the least. The ground, laid out in squares of 12ft., will contain something over 300 trees; that allows for each year's stripping 100 trees, giving two tons and a half, which, at the moderate figure of £3 10s. per ton, gives the return of £8 15s. per acre—a very handsome return, and a certain one, for the labour invested. There are immense areas of ground about Melbourne that have become exhausted that would suit the wattle very well, and I should think would give payable returns.

"TANNIN."

WATTLE LEAVES AND ASH.

TO THE EDITOR OF THE "AUSTRALASIAN,"

SIR,—I have been informed that wattle leaves make a more delicate tan than the bark. As it would increase the value of the tree very much, if so, information on that point would be of much service to strippers and growers of the wattle. Perhaps some tanners would kindly inform us the market value of the leaves, if any, and how and what time they should be gathered? I believe, also, the ashes of the wood contain a large amount of potash, valuable in making soap. Information on this subject would also be very interesting, and perhaps valuable to many besides ENGINEER.

Sandford, March 13.

GROWING WATTLES FOR BARK.

SIR,—I see Mr. Mirams has by a communication to the Chief Secretary drawn his attention to the importance of a systematic cultivation of wattle trees for bark. Would you please to reproduce a communication on the cultivation of the wattle which appeared in your columns about seven years ago, giving mode of cultivation, length of time to wait, cost per acre, and product from same, or perhaps some information of recent date? Why I ask for it is because I have been urging my neighbours, who have 10 to 30 acres of good land now being laid bare by their vines being uprooted, to cultivate wattle, and they only laugh at me for it. I have not gone into the system of wattle-farming by systematic cultivation, though I am devoting some attention to it, having purchased some 500 acres of grazing land, which is full of young wattle, and by thinning and trimming up I hope to produce some tons of bark. Many of my neighbours would like to know if others have tried it, and with what success.

Sir, whilst I am willing to grow wattle and devote some attention to it, I am disheartened by the appearance of a disease among wattle equally as destructive as the phylloxera vastatrix among vines. I refer to a grub which

attacks the tree when about three or four years old, and quickly destroys it, rendering the bark useless.

Parliament by its action in the vine disease has shown that it regards the stamping out of the disease as of national importance, and is not the destruction of wattle trees a national calamity? If it be true what Mr. Mirams says, that in three years three-fourths of the tanners of Victoria must close their establishments, will not that result be more disastrous to Victoria than the vine disease; and if Parliament votes money to up-root young, healthy vines because a few vines are diseased in order to prevent it spreading, ought they not to take similar action in respect to wattle trees, in order to keep the tanning establishments at full work. If these industries are closed hundreds of men and boys will be out of work, and they, with others indirectly affected, will be pushing Government to find relief works. I have not seen the report of the Wattle-bark Commission, therefore I do not know what it contains. But this I know, Sir, very few people care anything about wattle-trees, they are regarded as a nuisance in destroying grass, and as an indication of poor land, hence I know many persons with hundreds of acres of land cutting them down as soon as they appear. Trusting that some one of practical experience will give some encouraging statements to this, and that extracts from the commission's report will appear,—I remain, &c., WILLIAM HAM.

Fairview, Waurn Ponds, March 13.

SUGAR CULTURE IN INDIA.

TO THE EDITOR "FRIEND OF INDIA."

SIR,—I was much interested in an article of yours in your issue of the 6th February, which has only just reached this out-of-the-way place. In it you urge that sugar-planting should become a remunerative enltivation in India. As I am in Mauritius, a veritable little island of sugar, I fancy that some remarks from this part of the world may prove interesting, and thus these lines.

Let me first say that I have had ample opportunity of seeing the ordinary Indian sugar crop, and being some years resident in this island, seeing the working of estates, &c., &c., such information as I can give is based upon experience.

I fully agree with you that the cultivation of sugar-cane in India would be very remunerative, and would prove a safeguard for many in case of a failure in the *dhân* crop, but there are necessarily some considerations. I should say, in the first place, that capitalists should take it up, such as have the means for erecting mills for the manufacture of sugar. India should not remain content with the manufacture of molasses or "goor," which can never pay, but estates should be formed either with tenant-ryots or directly belonging to the estates, so as to ensure a labor market, so much needed in times of depression of the ordinary agricultural trade. In speaking of a labor market, I am aware that indigo supplies a pseudomarket, but with its systems of compulsory crop and "adha bhaut," it is hardly worthy of the name. It is a necessary evil perhaps, still an evil, and as such, can hardly be looked on in the light of a support in case of depression in agriculture.

Manure is required in sugar cultivation here—guano, night-soil, and engrais of different kinds are used plentifully; and in India, where the soil without a doubt is weak and over-worked, manure is equally required. With reference to this, I see some remarks of yours in your issue of the 27th February on an article in *Vanity Fair*, by a modest "Non-agriculturist," in which he wonders at the large quantities of produce conveyed to cities without any return being made to the soil which produced them, and comes to the conclusion that it must mean destruction of the soil, only giving it time for its final accomplishment. Every one must grant this as a truism,—it is distinctly burning the candle at both ends. But why is not the night-soil made use of in all the large cities in India? It would be getting rid of an impurity in nature's own way, and without doubt the closer the imitation the more effectual the result. Our small brains in attempting to follow a law can never do better than copying the Lawgiver. Let us call it natural, to be better understood. It always stikes me that the system of drainage by flushing, as adopted in tropical climates, is open to much objection. Comparing it with a status of no sanitary arrangements, it is an improvement, but it is far from perfect, especially as a mode of conveyance for animal excretions. It must give rise to malarial emanations from an impregnated soil somewhere, be it far from, or approximate to, the centre of population, depends upon the ability of the engineer; but to make it innocuous would tax the brains of the engineers and health officers combined, if a system of flushing is adopted. And why? Because all malarial emanations of a really dangerous nature are combination of hydrogen, and hydrogen is supplied *at libitum* when the animal matter is undergoing putresence; in other words, chemical action has commenced, and chemical affinity increased, and thus liberated oxygen remains virtually the sole agent on the field to battle against the odious compound formed; and this especially refers to tropical climates, where, under solar action, the process is more rapid. Where there is fluid matter in nightsoil, the difficulty to disinfect is increased tenfold. Flushing means merely a motive power for its removal, and its absolute removal, and that alone, is the sole conditions in which the drainage system for *animal excreta* can be deemed innocuous. Dry systems are much preferable. When I was in Bengal I was not aware of a single company started for the removal of night soil as an "engrais" or manure company.

There are many such companies here, and so remunerative are they, that they supply all apparatus for each house and undertake porterage, &c., gratis, if within a certain radius from the town. These companies are under strict municipal laws, night-soil being removed by a certain hour in the morning, and with all difficulties in legal matters, disputes, &c., they pay their shareholders admirably. Such manure is supplied to the sugar estates. Another manure is supplied from cane-refuse on the estate, the "bagas" (cane-leaf) and more woody portions of the cane supplying fuel for the mills. Why should not such a system be adopted in India?

Now with regard to labor, India has much the advantage. From R4 to R6 would amply satisfy the Indian laborer upon his native soil. Here from R6 to R10, with rations (equal to R4), housing and medical care, is not sufficient to keep laborers from day work; in fact every year they are leaving estates in larger numbers, and still sugar pays, and pays well here. Again, with regard to the labor which has to be bestowed on the soil, you have the advantage far and away. To describe sugar-cane fields in Mauritius of the ordinary kind, I should say—take one of you fields and pile all the stones you can find (from the size of a brick to a considerable boulder) on the soil and under it, and you can form some conception of a really productive field in Mauritius. Still the labor in removing the stones, and planting the cane in such soil pays and pays, well, and why should it not pay in India? Stones, I grant to a certain degree, retain the humidity of the soil, still a fair system of irrigation would attain the object better, and they are only awaking to the knowledge of that fact here now.

The soil here can only be marked by dint of crowbar, "pioche" (*jowrah*), and surely such labor far exceeds that which would be bestowed upon six times the area of Indian soil. Now for the price of land. There is hardly need of comparison. Cane land here fetches from R100 to R300 an arpent, its value depending upon its proximity to a stream or irrigating canal; but actually cane can grow with a small amount of water, when compared to your main staple *dhan*, and I have seen it yield an admirable crop in a dry year; in fact, too much moisture decreases the quality of saccharine matter. Hurricanes are far more destructive to a cane crop than drought, which is a great consideration for India; still I am afraid the monsoons would do a deal of damage in India if the crop ripens, as I fancy it does, in the cold weather, as the plants would have attained a breakable height. Here the crop ripens in July, when everything is comparatively quiet; and February and March are the months to be dreaded, as the canes are fairly high, and the months are in the hurricane season. So far, I think, India has every advantage over Mauritius, the liability to gales being put on a par. Now comes the main question before we can ensure cane cultivation to be remunerative in India.

Does the native of India know anything about its cultivation? No doubt I am no authority, but I should say he knows simply nothing about it; and your position certainly reminds me of burning the candle at both ends, but happily it can be remedied. What I mean is just this: that when the subject of sugar cultivation is urged for India, it strikes me that all your skilled labor is in other lands—Mauritius, Demerara, and elsewhere. Emigration was a needful outlet, but why should there not be a fair exchange? New blood is required at every labor market. I have rather a sad answer to make, and certainly a correct one. It is because there is not sufficient protection of the returned emigrant against the fiend *caste prejudice*. I have had ample opportunity for ascertaining the cause from returned emigrants. They enjoy a temporary quiet as long as their hard-earned savings hold out, and then caste shows itself, and so they return to seek what they can't find in their native country, comparative ease. And how is this? Well, in this manner; the emigrant comes out unmarried or virtually so; he marries (as the indignant old lady would say) goodness knows who; he necessarily has a family of nondescripts, and there is no doubt about their reception by his caste brotherhood in India. It would certainly need a bad man to adandon his flesh and blood; and be is not the man you require, though I very much question whether such is not the only stamp of man you receive back; and the mass return exiled for life, for one lesson with its attendant expenditure is enough. But the question is far from a hopeless one—very far from it, thank Heaven; to my simple mind it seems rather hopeful. I mentioned that capitalists should take up sugar cultivation as a basis to the system, and why?—because, I imagine, they will necessarily require a skilled labor market; in other words, they will, *nolens volens*, form the basis of a protective system by amassing a small colony of returned emigrants who will virtually be independent of caste prejudice in their brethren without, and so will earn a comparative rest and prove useful to both countries. I will clearly impress you with the fact that I mean both countries, as an outlet is urgently required for the time expired immigrant here. A village system is in course of operation here, but at what cost? We have a limited area, and the Indian population is already in excess. The result of the village system must ultimately mean a withdrawal from necessary estate labour; fresh ship-loads of coolies from India; a very large surplus population; and in fine, collapse of the labor system, and necessarily a decrease of revenue. Such is my opinion, and, humble as it may be, I think it would be well to have it ventilated; at any rate, skilled labor is available, new blood is in requisition, why cannot an exchange be effected? India would certainly gain by the transaction.

The common kinds of canes grown in Mauritius are the following:—

Bois rouge—Branche blanche; Fochego.

Bamboo.—Lousier; Riband cane.

Scambine.—Naz.

There are many others, and they can all be obtained from the Botanical Gardens, Pamplemousses, Mauritius. I must apologise for taking up so much space, but the subject can hardly be confined into a small compass. Should you require information on certain points, I shall be glad to be of use; and on your mentioning the heads upon which information is required, I shall do my best to supply it. "Vanilla" cultivation I should like to have entered upon, but space and time will not permit. However, on another occasion I may enter upon it should you care to find space for it.

CRUX.

"PEARL TREE."—We are glad to get this name, but have forgotten where we saw it, for one of our prime favorites in the way of ornamental shrubs, one for which we before only had *Exochorda grandiflora*, which does not translate into anything intelligible. Our shrub, now twelve years or more old, is over 10 feet high, has a tree like habit, and is in spring a mass of white. The English journals have been discussing its hardiness at various places in that country. As we have had the thermometer at 15° and 20° below zero, and not a twig injured, we regard it as hardy in this country also.—*American Agriculturist.*

POULTRY HOUSE CONVENIENCES.

The raising of poultry year by year is receiving more attention, and anything that will add to the ease in management is gladly welcomed by the admirers of the feathered tribe. The practice among farmers of letting their poultry roost about the farm buildings, upon harrows, plows wagons, and farm machinery is growing less each year, as many of them are building suitable poultry houses. In the engraving is shown a neat and handy arrangement in perches, of which *r*, *r*, *r*, are scantling, eight feet in length, two inches thick, and three inches wide, made of some tough light wood. The upper ends are hinged to the side of the building, four feet apart, and are connected with roosts or perches one inch in diameter, or what is better nail octagon strips fast to the supports. Perches should be placed about one foot apart. At any time when it is desired to gather up the droppings, the end of the frame-work is raised sufficiently to engage with the hook on the support *n*, the whole arrangement being up out of the way, for thorough cleaning. At the corner of the building, opposite the roost, is placed a box, *p*, containing ashes, road dust, etc., that the fowls may dust themselves. The box should be two feet square and about one foot in height, and should be kept half filled with dusting material, more particularly during winter. In the corner is placed a box, *e*, and should contain a supply of gravel and broken oyster or clam shells. The foregoing conveniences cost but little and will prove valuable additions to any poultry house.

—*American Agriculturist.*

CAFFEIC ACID FROM CUPREA BARK.*

BY G. KORNER.

The raw material upon which the author experimented was supplied to him by the Lombardy Manufactory of Chemical Products, and was distinguished from other qualitiesof cinchona bark by giving a reddish-violet colour when a solution of potassic hydrate was added to its aqueous extract. The most important fact discovered by the author while pursuing his researches was that during the manufacture of sulphate of quinine from this bark there is formed a notable quantity of caffeic acid, which is evidently produced by the breaking up of a complex substance existing in the bark in company with the alkaloid. The caffeic acid is found in the mother-liquors as caffeate of quinine. This salt is obtained by repeated evaporation and fractional crystallization in slightly coloured mammilar crystals, which on being treated with dilute sulphuric acid and exhausted with ether sometimes give caffeic acid, but at others an acid which is obtained in such small quantities that it has not yet been studied. The mother-liquors turn brown when in contact with the air and deposit on the sides of the vessel containing them a dark powder, resembling in this respect solutions of caffeic acid and protocatechuic aldehyde. They also often give off an odour closely resembling that of vanilla.

In order to avoid any doubt on the matter the author prepared from the cuprea bark acid some bimethylcaffeic acid and its methylic ether, which both gave precisely the same characteristics as the corresponding compounds prepared from the caffeic acid of Hlasiwetz.

The fact of having produced caffeic acid from the *Cinchona cuprea* as a product of the splittiug up of a complex substance contained in it, that acid only having hitherto been obtained by a similar splitting up of caffeotanuic acid from coffee, furnishes an additional proof of the relationship which exists between the coffee and cinchonaceous plants, Zwenger having already obtained quinic acid from the former. With several extracts of other species of cinchona bark the author could not succeed in obtaining this acid.—*Pharmaceutical Journal.*

ON THE LOSS OF NITROGEN IN PURCHASED MANURES WHEN APPLIED TO CROPS.

BY J. B. LAWES, LL.D., F.R.S.

There is one great advantage that writers on the subject of Agriculture in the United States possess over the same class in Great Britain; they are sure to obtain an impartial

*From the *Annali di Chimica* for June.

hearing. In the United States a farmer, on coming across any views, or statements on the subject of agriculture that are new to him, asks himself the question, are these true; and, if so, what benefit can I derive from them? In Great Britain, from the conflicting interests of the owner of the land, and the occupier who pays an annual rent for the right to cultivate it, the teachings of science are likely to be praised or blamed accordingly as they affect the interests of the owner rather than those of the cultivator of the soil. A few years ago, when public attention was directed to the vast increase in the amount of agricultural produce sent from the States to England, there were many who put forward the view that, by a more liberal application of capital to the soil, we could grow all the wheat required to feed our population. Under these circumstances I thought it my duty to cautiou tenant farmers against paying too much attention to statements which were uttered by those who had no experience in either practical or scientific agriculture. I accordingly delivered a lecture before a farmers' club, in which I endeavored to show, by the teaching of my own experiments, that a higher system of farming was not so certain a remedy for falling prices as some wished them to believe.

In a letter recently published in a paper devoted to field sports, which I have been informed is much read by the owners of land, a writer, who signs himself "Agricola," makes the following observations:—"Certain pamphlets of Mr. Lawes have done intolerable mischief in giving a false coloring to the service higher farming might render in enabling British farmers to tide over the present crisis," and he goes on to say that we have the counterblasts of M. Georges Ville to send all unsubstantial utterances beyond the domain of rational consideration!

If in speaking of the immense influence which such nitrogenous manures as Ammonia, or Nitric Acid produce upon the growth of our ordinary cereal crops, I had pointed out that, owing to the high price of these substauces, it was by no means certain the increase in produce would pay for their application; and consequently it would be desirable for the United States farmer to exercise some caution in their use, I think it is hardly possible to believe, that any one in the States could suppose such a caution would be productive of evil.

In another case I was rather amused at a correspondence which I lately noticed between M. Georges Ville and some one who had called his attention to my views with regard to the sources of the Nitrogen in vegetation, which were altogether antagonistic to those entertained by M. Ville. M. Ville, in his answer, stated that he had heard of the existence of a pamphlet on the subject, but that hewas so much engaged in showing how Foreign Competition could be best overcome, that he had not time to look into it, but that he would do so, in order to see whether it would be necessary for him to answer it himself, or whether he should leave the task to one of his pupils.

With regard to the subject of Nitrogen, the views I am disposed to entertain may be briefly summarized as follows:—(1) That the soil and not the atmosphere is the main source of the Nitrogen which we find in our crops. (2) That in the application of manures containing Nitrogen, more or less loss of that substance is always incurred; and consequently, if the object is to obtain any given amount of Nitrogen in the produce, the application in the form of manure must be largely in excess of the amount required. In everything relating to the competition between Europe and the United States; between the vaste stores of untouched fertility of the one, and the comparatively exhausted stock of the other, the question of Nitrogen is one of paramount importance. I am not aware myself of any writer, practical or scientific, who has accepted as a fact, or even entertained the idea, that in the application of Nitrogen in purchased manures a considerable loss is incurred. This loss in a substance of so costly a nature is a matter of great economic importance. The view generally held, I believe, is that no loss takes place, and further that by a small application of Nitrogen, a farmer not only recovers in the crop all that he has applied in the manure, but a good deal more. This, according to M. Ville, is the economic function of our root crops, which, when well supplied with minerals, and a small amount of Ammonia, get what more they require of this element from the atmosphere. The following are the views of this writer with regard to a rotation: "That some crops demand all the Nitrogen they require to be supplied to them; others require a small amount, which enables them to obtain a good deal in addition from the atmosphere; while others again can obtain the *whole* of the Nitrogen they need from the atmosphere." This explanation appears so simple and clear that it seems quite a pity to say anything that could throw a doubt upon its accuracy. I will now endeavour to show what loss of the Nitrogen in the manure has taken place in our own experiments on the growth of potatoes at Rothamsted. In order to measure the effect of Nitrogen, and also ascertain whether any, and if so what amount of loss has taken place, our plan has been to grow the crop continuously with mineral manures alone. We consider that by this means the crop avails itself of all the sources of Nitrogen at its disposal, whether they be derived from the soil or the atmosphere. When, in addition to the same minerals, Nitrogen in some soluble form is applied to the potatoes in another experiment, we consider that the increase in the crop over that grown by minerals alone, is due to the Nitrogen of that manure; and, further, if we deduct the amount of Nitrogen in the crop grown by minerals alone, from the amount contained in the crop grown by minerals and Nitrogen, the residue, when compared with the amount of Nitrogen applied in the manure, will give us the measure of the loss. I must observe, however, that this experiment requires to be continued for a good many years before any safe conclusions can be drawn; first, because of the great influence of favorable or unfavorable seasons; and secondly, because it is only by the aid of time that we can ascertain whether the Nitrogen applied, but not recovered in one crop, is available for those which succeed. The more favourable is the season for the growth of a crop, the better will the crop be able to avail itself of the stores of manure furnished by the soil and atmosphere. At Rothamsted, the season just passed was very favorable for the growth of potatoes, I therefore select this year's crop, not as indicating what might be the average loss of Nitrogen applied in manure, but to show how very serious may be the loss, even under exceptionally favorable conditions. The following table gives the number of bushels of potatoes of 50 lb. each:—

TABLE.

	Bushels per Acre.
(1) Potash, Soda, Magnesia, Superphosphate	265
(2) The same as (1) with 400 lb. Salts of Ammonia ...	484
Gain by addition of Ammonia	219

It is quite evident that the mineral manures enabled the potatoes to gather up a large amount of Nitrogen; and that further growth was only arrested for want of more Nitrogen, is evident by the much larger crop grown when a manure containing that substance was used; this fact is still further confirmed by the analyses of the potatoes grown by mineral manures alone, which show a very low percentage of Nitrogen. Assuming that the ordinary potatoes in a dry state contain one per cent of Nitrogen, these potatoes contained one-sixth less than that amount, and it is probable that under such conditions no further growth was possible.

We now come to the loss of Nitrogen. The 400 lb. of Sulphate and Muriate of Ammonia are estimated to furnish about 85 lb. of Nitrogen; taking the potatoes grown by mineral manures alone at 26 lb., we find in those grown by Ammonia and minerals 66 lb., or an increase of 40 lb.; but as we supplied 85 lb. in the manure, we have recovered something less than 50 per cent of the amount supplied, and this, too, under the influence of an unusually favorable season! Taking an average of seasons, it would be much nearer the truth to say that not more than one-third of the Nitrogen supplied is recovered in the crop. Potatoes contain 25 per cent of dry matter in every 100 lb.; if we take a bushel to weigh 50 lb., 8 bushels will weigh 400 lb.; which amount is equivalent to 100 lb. of dry matter, and will contain 1 lb. of Nitrogen.

To obtain this 1 lb. of Nitrogen in the produce, we find it necessary to apply 3 lb. in the manure, and as the Nitrogen costs about 25 cents per lb., this large difference between the amount supplied and that recovered becomes a very serious consideration.

I might further observe that as our experiments are conducted with more care and attention than could possibly be given to crops grown under the ordinary operations of agriculture, I do not think it would be safe to reckon on a smaller loss than that which we have incurred, and the probability is that it might be much larger.

The general conclusion to be drawn from these experiments, as well as from those upon root crops in general, such as turnips, mangels, and sugar beet, is that they do not obtain their Nitrogen from the atmosphere; and that, when supplied with that substance, the amount recovered in the crop is very much less than that supplied in the manure.—*American Agriculturist.*

DURABILITY OF INVERTED OAK POSTS.—Experiments have proved that oak posts put in the ground in the same position as that in which the oak grew—*i.e.*, top upwards—were rotten in 12 years, while their neighbours, cut from the same tree, and placed top downwards in the soil, showed no signs of decay for several years afterwards. The theory is that the capillary tubes in the trees are so adjusted as to oppose the rising moisture when the wood is inverted. —*The Garden.*

GRAFTING THE CHESTNUT.—Many who find trees, the nuts of which are unusually fine and large, naturally desire to propagate them. They try the methods used with ordinary fruit trees, and rarely succeed, and we are frequently asked how the grafting should be done. In Europe the method known as flute grafting or budding is generally followed, but one who has had no practice with this, would be very apt to fail, as it often does in the hands of skilled workmen. E. Clausen describes in a recent "Revue Horticole," a method which has given him such good results that he makes it known. He grafts in the latter part of June, or when the shoots of the season are sufficiently mature, as it is these which serve for both stock and cion. He makes an incision down through the centre of the terminal bud, and about an inch and a half long. The cion is a shoot of the current season, containing a terminal bud only; it is cut wedge-shape, and carefully inserted in the cleft of the stock. When the cion is properly fitted, it is carefully wound with woollen yarn, waxing of any kind being thought unnecessary. To shade the graft several of the leaves on the stock below the insertion are brought together and tied above it in such a manner as to afford it protection from the sun and wind. Mr. C. considers this shading essential to success; and it is all the more necessary with us.—*American Agriculturist.*

MULCHING.—The great benefit accruing from this practice can scarcely be over-rated, as not only does it prevent red-spider from attaking the leaves of Vines and Peach trees, but it keeps Peas and Beans and other vegetables growing and bearing when they would otherwise fail. To water without it is next to useless, as the washing the ground receives causes it to crack open and let in air, and not only that, but roots are attracted to the surface, where they quickly suffer and die, whereas when shaded by a mulching the feeders multiply at a rapid rate, and they remain healthy and full of life and activity under the covering. For Vine borders nothing is better than very short stable manure, which lies light, and though not over-rich the Vines may be fed in another way by giving them plenty of sewage. This is always better than laying on close solid matter, such as cow-dung, which, after it becomes caked together, is nearly impervious to air, and air is essential to the soil of a Vine border to maintain the roots in good health. To break up the surface and dig manure into their borders, as some do, is a great mistake, and all that should be done is just to hoe the surface with a hoe to destroy weeds, and then pop on the mulching at once. If this be carried out and a thorough soaking given when Vines are growing and swelling a crop the effect may be seen at once at the rapid increase in the size of the berries, and the same with Peaches and Nectarines or young Apples and Pears, which without help when taxed with a crop, often look very much distressed with their loads. Another crop that pays well for mulching is Celery, which in dry hot seasons seldom if ever does well without it. Tomatos, again, are greatly benefited by its help, as they set with more freedom and bear the finest of fruit.—J. SHEPPARD.—*Gardeners' Chronicle.*

THE MANGO FRUIT (*Mangifera indica*) it may be presumed in an unripe state, is being tried in the United States in medicine. Dr. Linguist, who has introduced it, states (*Practitioner*, p. 220) that it is an astringent with a special tonic action on the mucous membrane, and that in the treatment of hæmorrhage and muco-purulent discharges he knows of no equal to it.—*Pharmaceutical Journal.*

LEMON JUICE.—In an interesting account of the chemical industries of Italy (*Chemiker Zeitung*), the surprising fact is pointed out that although lemon juice is made in many places in Sicily, when it represented in 1881 a value of nearly three millions of francs, the whole being exported, chiefly to England and France, yet in Italy no one appears at present to be engaged in the manufacture of citric acid. Up to 1880 one factory existed at Messina, but when that town was made a free port it had to stop operations.—*Ibid.*

COCA.—In the *Boston Medical and Surgical Journal* (p. 221), Dr. A. P. Mason, gives an account of experiments made on himself with coca. He has arrived at the conclusion that coca had a good effect upon him both mentally and physically; that it almost always produced exhilaration and without exception prevented fatigue. This he believes to be due to stimulation of the nervous system and retardation in some way of the process of metamorphosis, so that work is done with less expenditure of force with than without coca. The experiments were made with the fluid extract. Coca leaves are so very variable in quality that experiments made with them cannot be said to be so satisfactory as if made with either the crystalline alkaloid, cocaine, or the volatile oil, hygrine.—*Ibid.*

BARON F. MUELLER, the well-known botanist, Director of the Botanical Gardens at Melbourne, defends, in the *Gardeners' Chronicle*, p. 278, his use of the words "algs" and "fungs" instead of "fungi" and "algæ," on the ground of conformity with the terms mosses and lichens. In the same way he uses the word "eucalypts" just as we say "elms" instead of "ulmuses." His use of the diminutive termination "let" in "stalklet," "fruitlet," etc., and other alterations proposed by him, are, it may be hoped, the commencement of a change of foreign botanical terms into more easily understood English ones, a change which would certainly render the study more easy and pleasant than it is at present, and tend to remove the reproach that botany is a science of hard names.—*Ibid.*

SPONGES.—The *Weekly Drug News* (Sept. 1, p. 3) contains an article on sponge fishery in the Bahamas, from which it would appear that the Governor of those islands has approved a law passed in a special session of the Legislature to prevent the use of dredges, which have for some time past been used with considerable success instead of the pole and hooks. The penalty for violation of the law is a fine of 100 dollars and confiscation of the vessel on which a dredge is found. The law seems to have been passed under pressure of popular clamour, and in forgetfulness of the fact that there are many sponges to be obtained at a depth where the use of the pole and hooks is impracticable, and that the use of the dredge would have increased the trade without affecting vested interests had its use been confined to fishing at such a depth. How for this law will affect the price of sponges remains to be seen.—*Ibid.*

BURNS AND SCALDS—IMPORTANT REMEDY.—Bicarbonate of soda, that is the common cooking soda, for most kinds of burns. The soda, and the carbonic acid so readily set at liberty from it, have anesthetic, antiseptic, and disinfecting properties—all highly beneficial for burns. For slight burns cover all the injured parts with a layer of powdered soda. For deeper burns, but where the skin is not broken, dip linen rags in a solution made by dissolving about one-third of an ounce of the soda in a pint of water; lay the rags on and keep them moist with the solution. For very severe burns, followed by suppuration (formation of pus), apply the rags in the same way, keeping them moist; but frequently exchange them when dry for fresh ones, and carefully wash off, with the soda solution, any matter that has accumulated underneath, so that it may not be absorbed into and poison the blood. Leading European medical journals give numerous instances in which, by the above treatment, extensive burns of very severe character have healed speedily, leaving little scar. —*American Agriculturist.*

AN INDIAN PLANTER ON THE CEYLON TEA ENTERPRIZE.

We desire to draw attention to the very encouraging testimony borne (below) to the fitness of Ceylon for tea growing, from elevations of 70 to over 6,000 feet above sea-level ; and of the good quality of our teas when properly prepared. We may mention in this connection that we have had a sight of reports from several tea estates, which generally confirm the hopeful view taken by "Cha." On one estate we observe that 742 lb. of green leaves were plucked on one day, the result being 186 lb. of made tea, or 1 lb. above the usual estimate of 25 per cent dry leaf to green. On another day 598 lb. green leaves gave, not merely 149 lb. 8 oz. which were due, but 162 lb. On other days the dry tea was considerably short of 25 per cent, but at the end of the, week 2,808 lb. of green leaves gave just the exact quantity which "should be" *viz.*, 702 lb. Between 1st January and 22nd October this estate had turned out 24,278 lb. of made tea, an increase of 16,152 on the quantity made in the similar period of 1881. In the case of another estate we find the dried tea was 948 lb., instead of 874 at 25 per cent ; but with still another the process was reversed, the actual quantity being only 572 lb. instead of 594. Again we get 351 instead of 334 and 1,196 instead of 1,182, and 9,408 instead of 9,336 lb. No doubt leaves gathered in perfectly dry weather give a better per centage of made tea than flushes gathered during heavy rain. The general result is one-fourth of dry tea to green leaves, and our Indian tea planter estimates 700 lb. of dry tea per acre for low estates and 400 for high, as likely to be attained.

DEAR SIR,—I promised to write to you now and again on Tea in Ceylon, and ought to have done so before now, but I thought it would be better to wait until I knew more of the climate and land I was writing about ; so that I should not lead any one astray. I can now write to you on the subject with more confidence, having spent a year among you, during which time I have seen tea growing from 70ft. above sea-level to over 6,000ft., and I am well satisfied with the growth at all elevations, and I no longer doubt that Ceylon will yet be a great tea-growing country, and the sooner all who are interested in tea put their shoulder to the wheel to send to market teas that will sell at a profit, the better. This can only be done by giving careful attention to the plucking and manufacture.

Ceylon teas are now begun to be known in the market, and we should give our careful attention to the manufacture, so that our teas will get better known. We have all a great deal to learn about the growth and manufacture of tea, and none of us should be too proud to be taught. We can all learn from each other, and should be all willing to assist each other, as all are striving for the same end ; that is to make tea a profitable investment. This can be done and why make a secret of the fact ?

Now that our old love, coffee, has forsaken us and that tea can be grown in the old fields among the coffee, why not plant tea among the coffee, but leave our old love to shelter tea, and should our old love give us a good crop cut down the tea within 6 inches of the ground, which will only improve the new love and make her flush and blush better than ever ?

I am glad to see that Ceylon teas are improving, and I hope that they will continue to improve, although up to the present time there is some awful rubbish shipped from Ceylon, from some of the greatest tea growers in the island—men that should ere this know what good tea is and how it ought to be made, but still they will continue to ship rubbish to the market : in some cases they are ashamed to put the plantation mark on the chests. If they send tea at all to market, they surely should put the plantation marks on the chests, and, if any of us don't know how to make good tea, why should we not acknowledge the fact and be taught by some one that may know more than we do ourselves on the subject. We can never be too old to learn. I would advise all the Ceylon tea planters to exchange samples with each other and to visit each other ; in fact I would advise tea proprietors to give their Superintendents 15 days' leave each year to go round and visit other estates. If they should see nothing to copy, they may see a lot to avoid ; the mere fact of exchanging ideas with each other does a lot of good.

I have no longer any doubt about the profitable growth of tea in Ceylon, and I am sure that it can be profitably grown from 20 feet above sea-level to 7,000 feet. The flavour of the high-grown tea will make up for the shorter yield that one would get at a high elevation.

I consider with careful management that tea could be worked up to 400 lb. per acre in the highest elevation in Ceylon, and in some districts in the low country I would not be at all surprized to see an average of 700 lb. per acre reached, and what I mean is not 400 and 700 lb. of rubbish but of good tea that should average 1s 5d per lb. I could mention several estates that will turn out more in three months this year than they made in twelve last year, and all among that so-called poor soil of Avisawella and Ruanwella ; the richest tea soil in the island which will yet be the great tea districts of Ceylon.

I am glad to say a lot of land is now taken up for tea in the lowcountry, which will increase the value of the oldest pioneers of the district's estates, who well deserve to be rewarded for going into a district that was thought to be feverish and deadly. Had the men that I am now thinking about gone in for tea in the way they went in for coffee, how different would their banking account have been today.

I understand that some enterprizing proprietors are not going to content themselves with growing tea and cocoa only, but they are going to start a daily steamer, which will do a lot to open out the districts and ought to pay the shareholders well.

Wishing good luck to the Kelaniganga Steam Navigation Company,

CHA.

INCREASE OF COCOA OR CACAO CULTIVATION IN TRINIDAD.

In the first half of 1882, the exports of cacao had risen to over ten-million of lb. against an average of eight-millions, and *Trinidad Chronicle* states—

The laying out of new land in Cacao goes on unceasingly, as it has been doing over the last 12 or 14 years, the great majority of the plots small at first owned by small people *ci-devant* laborers and contractors, and cultivated by themselves but by degrees forfeited to the merchants to whom they are indebted for advances, and by amalgamation converted into good-sized properties counting acres by the hundred and (the cacao) trees by the tens of thousands. There is no movement corresponding to this in cane ; and the opening of new cane estates, on any scale—and a large one, *ab ovo*, is the rarest of *rara aves*—goes on slowly indeed. It cannot be done

without capital, a capital of thousands sterling, whilst a very small purse of savings will give a man courage to buy and lay down, in cacao and provisions, a little plot of ten or twenty acres. Yet it is pleasing to note that where a new line of road cuts through virgin land, as at Conupia, by the railway, buyers start up from the ground as it were, that no one dreamt of, men in town successful in business or trade whom no one had previously credited with a taste for cultivation, yet who on being tested have been found to be gifted with a somewhat Mechian capacity for the pursuit quite equal to and in some respects possibly better than old clod-plodders to the manner born, carrying into the new practice the habits of foresight and perseverance that had gained them their first successes and yielded them the means to enter on an untried venture.

Mr. Fabien's place, *Enterprise Farm*, a piece of 300 acres, lies on the opposite or east side of the railway. He has a mile of frontage on the line, and is about a mile from the railway station. The farm presents, for Trinidad, a very varied scene : Liberian coffee is represented by 5,000 trees, the St. Anna' hybrid coffee by 15,000 plants; the Tonka-bens tree by 1,000 plants, at present about 5 feet high and which are expected to come into bearing in four years from this. Of tobacco, he has 25 acres, managed by Mr. Anderson who brings Jamaica experience to the task : 5-6,000 lb. have been cured or are now curing, of this crop, and some of it is on sale in town. Mr. F. being apiarian as well, has imported some Italian bees, got sunflower seed, hives, and books and journals on the subject from America; but in this line cannot yet speak of success, finding the 'Qu'est ce qu'il dits' even fonder of his bees than himself, and that the latter were attacked also by a certain species of ant. In time, no doubt, he will find a way to neutralize these attacks and get a profit from his bees. He has succeeded in making a Queso de mano,—little hand-made cheeses weighing a pound, cream white like the big Llano cheeses of Maturin we get from the Spanish Main, but much cleanlier. They have the same peculiar sourness and absence of fatty richness, though made from unskimmed milk we are assured, but of a flakey texture that some admire. For these cheeses, Mr. F. says, he has a demand for more than he now makes, though he gets half a dollar a lb. for them. But his chief object in keeping a stock of milk cows was to supply the town with pure milk, a very laudable idea, to which a great many will wish success. The milk is brought to town by rail and has a remarkable keeping property. We are not sure we have exhausted the list of experiments—enterprizes we should rather call them, with those we have named. Enough has been said, however, to shew the new spirit that has been evoked by the opening of the Southern Railway—and the certain extension of settlement that follows the judicious construction of improved communications. Like causes, like conveniences produce like effects here as in Australia or America, though on a smaller scale. If our ruling minds, freed from other care, would direct their thought seriously to the subject, we are persuaded they could attract settlement to the island at a much faster rate than it is now progressing at; and would not every interest in the colony be advantaged thereby? Who can doubt it?

THE TROPICAL REGIONS OF AUSTRALIA.

Our readers are pretty familiar with the "Northern Territory" of South Australia, if it were but for the fact that the submarine telegraph cable by means of which all the world communicates with the Australian colonies and they with all the world, has its terminus at Port Darwin. Thence a land line was carried over an immense stretch of uninhabited country. Otherwise the management of the Northern Territory was not, until recently, happy, and its progress compares poorly with the progress of Queensland. But then Queensland may be said to be largely tropical and the portion not within the tropics is certainly semi-tropical, for plaintains and pineapples, in defiance of occasional sharp frosts, are cultivated in the suburbs of the capital,—Brisbane. While tropical Queensland, from Rockhampton northwards by Mackay, Townsville, Cooktown to Cape York, within 10° of the equator (about as far south as Point Pedro is north of "the line,") has made such considerable progress that the inhabitants are clamouring for separation, the few settlers in the Northern Territory of South Australia are raising the same cry just because of the limited progress made by the scene of their enterprize. Their great grievance at present is that of being made to pay customs duties like their southern fellow-colonists. If, however, they get the promised railway, there will be large compensation. But a third Australian colony, the largest of the group, Western Australia, has also a tropical territory, stretching as far north as 12° from the equator. In this region is the district of Kimberley with forty millions of acres of splendid, well-watered and well-grassed land. Here stock flourishes, notwithstanding the heat and the mosquitoes; but it is only natural that the culture of tropical products should be suggested in a region where palms abound in the "scrub" or "forest" as we should say. From the extract we take from the Perth *Inquirer*, it will be seen that our nearest neighbours of the "fifth continent" are under the impression that Sinhalese labour would be specially useful in the culture of coffee and cinchona. The Australians will soon discover, however, that it is to the densely peopled portions of continental India they must look for the labourers who can work in their permanently hot regions, and we have no doubt that Western Australia will speedily follow in the wake of Fiji, South Australia and Queensland in seeking to make arrangements with the Indian Government for systematic cooly immigration. The difficulty will be not with the Indian Government, but from the prejudices—in many cases the honest convictions of the Australian settlers themselves. Such a man as Joseph Cook, while predicting the grandest possible future for the "hundred millions" of Australia and a most beneficial influence for good on Asia as a result, joined in the protest against the introduction of Asiatics. The editor of the Sydney *Mail* very pertinently asks what the cottou crop of the United States would be were the Negro element to be removed. If pastoral pursuits alone were in question—and curiously enough, intense heat in Australia is compatible with good mutton and fine wool, good beef and strong horses—if pastoral pursuits alone were in question, of course, there would be no occasion for a mixture of races,—at least for special steps to introduce Indian coolies. But if sugar-cane, coffee, cocoa, and other strictly tropical products are to be grown, cooly labour, guided and aided by whites, is indispensable, and in all probability the design of Providence is that Asia should be re-acted on beneficially by yellow skins and black skins returning from Austral-Asia, imbued with the enterprize, industry, wealth, civilization and Christianity with which as labourers they came in contact. There is a

great wave of ethnic movement surging a-head, and the consequences are likely to be most momentous. That the wave is to be stayed by prejudices of race and colour and prohibitory laws, whether in America or Australia we do not believe.

(*From West Australian Inquirer*, Oct. 4th.)

Kimberley, it is generally believed, will some day be a great country. The prevailing opinion is that some parts of the country are admirably adapted to the growth of sugar and other tropical products. If so the land will rapidly increase in value, and we may hope to hear of establishments being formed similar to those in Queensland and in the Northern Territory. Queensland has established several factories, and is bringing over from the Polynesian isles labor in abundance. In our case, owing to our close proximity to India and China, our labor market would doubtless be supplied from those countries, and it would be superior to Kanaka labor, which is chiefly employed in Queensland. The growth of sugar-cane, coffee, cotton, and cinchona will doubtless be attempted. We shall take our readers over a sugar plantation in Fiji, where the labor is composed of South Sea natives. Rations for every man, consisting of 10 lb. of sweet potatoes, or 7 lb. of yams, are weighed out each morning. The day's work is limited to nine hours. Their pay is from £3 to £5 per annum, clothes being provided. The holes in which the cane is planted are six feet apart lengthways, the rows being four feet apart. The planting time consists from September to November, and in 14 months' time the crop is ready for cutting. In some cases the cane is fully 22 feet in length, and the average yield is 40 tons to the acre. The price of the cane is 10s. a ton all round. On the Rewa there are between 1,500 and 2,000 acres of sugar planted. Taking the lower figure at 40 tons to the acre, it gives a respectable total of 60,000 tons of cane, and as it takes 15 tons of cane to make one of sugar, a result of 4,000 tons is given which, at from £25 to £35 per ton, and assuming a medium figure, gives a gross value of £120,000. The price paid for the cane is 10s per ton, or, for 60,000 tons £30,000, so that there must be a considerable profit to the mill-owners, even after leaving a largemargin for expenss.

Coffee planting is another profitable industry. Nursery plants are at first planted in beds, in rows six inches apart, and but one inch apart lengthwise. The beds are generally 30 feet long by three feet broad. After eight or nine months those that do come up are transplanted, each being afforded a space of six feet by six feet, 1,210 plants going to the acre. It sometimes takes three years* to bring coffee to maturity; the average yield is 15 cwt. to the acre when the trees have had 5 years' growth. The price of coffee berries per ton is stated at from £100 to £110, so that between £70 and £80 is the yearly value per acre of a *bona fide* plantation.† Sinhalese labor would be well adapted to the cultivation of coffee, and plants could be imported from Ceylon.

The high value of the cinchona tree, from which the Peruvian bark is obtained, is known to almost everybody. Its cultivation is being encouraged in all tropical climates, and where its growth can be secured the profit is enormous. It takes about two years* before this precious bark can be stripped, and with proper care a continuous supply is obtainable. We have mentioned some of the tropical industries suitable to our north-west climate; we could add cocoa the vanilla, and tea cultivation, besides tropical fruits and other plants, but the three principal industries we have quoted show unmistakably that if the land is of the description it had been represented to be, an immense future is in store. In all probability the service we have so repeatedly advocated with the Straits Settlements, India and China, will be carried out; with the facilities this will afford inducement will be given to settle. The Government have no time to lose in carrying out their projected surveys, laying out town sites, declaring agricultural semi-tropical areas, and putting them in the market.

* Four rather.—ED. †5 cwt. per acre worth £20 would be a safer calculation!—ED.

ALOE FIBRE IN MAURITIUS.

There are now, we believe, some half-a-dozen public companies, with an aggregate capital of about £150,000, carrying on the growth and preparation of aloe fibre in Mauritius, and during the past twelve months considerable activity has been displayed in prosecuting the industry, which still seems however to be in its infancy. The local organ of the planting community gives the following figures, showing the export of fibre during the ten years ending 1880, but why those for 1881 should not have been included by August 8th we are at a loss to understand :—

	Kilos.	Value.		Kilos.	Value.
1871	8,331	R 4,370	1876	231,089	R 57,220
1872	69,368	46,340	1877	271,374	67,692
1873	77,994	44,162	1878	379,476	93,497
1874	248,506	37,488	1879	863,870	144,260
1875	—	31,453	1880	662,500	117,000

It will be observed that there was a very rapid increase in the three years preceding 1880, but that in that year, from some cause which the local historian leaves unexplained, the shipments fell off materially. Possibly, however, the clue to this decline is to be found in the fact that hitherto the companies engaged in the industry have done very little in the way of planting aloes, and even if they had, sufficient time had not elapsed for the plants to reach maturity. The tracts of land taken up have been already overgrown with wild aloes, furnishing a ready-made and gratuitous supply of the raw material, so that the companies' capital and energies have been devoted to the erection of mills and machinery for extracting the fibre, and to the construction of roads, &c. Now, it is obvious that under these circumstances the industry is not at present established upon what can be regarded as a thoroughly satisfactory commercial basis, since we are assured by the local editor that no data are available as to whether it will prove profitable when the present sources of supply within available distance of the mills have been exhausted, and it is necessary to produce it by cultivation. It is quite clear that, until this all important question has been answered, it is impossible to form any idea whether the enterprize is likely to develope sufficiently in Mauritius to take rank beside sugar.

It will be observed that the shipments of 1880 amounting to 662,500 kilos, or 12,566 cwt. 2 qrs. 15 lb., valued at R117,000, or a little over R9¼ per cwt., which, at 1s 8d per rupee, is equivalent to only 16s 5d per cwt. We understand that this fibre is used chiefly, if not exclusively, in the manufacture of rope and cordage, for which it is admirably adapted, but that this accounts for the low value placed upon it. It is almost certain, however, that if the aloe leaves were treated by Ekman's process, a fibre would be obtained fine enough for spinning and weaving purposes, the market value of which would be three or four times as much as the coarser material now realises. There is, moreover, another consideration favourable to the adoption of chemical in place of mechanical treatment, since much less fuel is required for the former than the latter process, and if the industry were to extend greatly, fuel would soon become a serious difficulty, as surplus megasse from the sugar estates is the only kind available in any

quantity. Under these circumstances, it is evident that in Mauritius there ought to be a good opening for the introduction of Ekman's system even though the bi-sulphate of magnesia should have to be imported from hence or from India. It is quite possible also that magnesite might be found on the island. —*Planters' Gazette.*

MICA.

An advertisement in the *Ceylon Observer* recently, indicated that this article is in request, and just as we were speculating over the purpose to which it is applied, we came across the following notice in an American journal :—

"MICA AXLE GREASE, PATENTED, 1874—Composed largely of powdered Mica or Isinglass, is the best and cheapest lubricator, in the world—the best because it does not gum, but forms a highly polished surface over the axle, reducing friction and lightening the draft ; the cheapest because it costs no more than inferior brands, and one box will do the work of two of any other make. Answers as well for Harvesters, Mill Gearing, Threshing Machines, Corn-Planters, Carriages, Buggies, etc., as for Wagons. Guaranteed to contain no Petroleum."

By a further curious coincidence, we have come across the following paragraph :—

"One of the chief uses of mica at the present time is for stove doors and lanterns, the fire resisting qualities of the mineral together with its transparency rendering it specially adapted for the purpose. But only the very clearest and best sheets of mica can be thus used. Vast beds of the substance exist in various parts of the country, for which, except the finest portions, as above mentioned, there is little demand. New uses will, however, doubtless be discovered and invented, for mica is made up of valuable materials. We notice among the recently granted patents two inventions in this line. One is for the manufacture of journal boxes of cement, ground mica and flour ; the ingredients are mixed, pressed into shape, and then baked. The other is an apparatus for reducing mica to an impalpable powder and preparing it for use as a mixer in starch gloss and oily compositions.

"Chemically regarded mica is made of silica, alumina and potash. Silica is one of the hardest substances in nature, known in its purest and most beautiful form as rock crystal. Alumina is another exceedingly hard substance. One of its most useful but impure forms is emery or corundum, now so extensively employed for grinding and polishing purposes. The most elegant and purest examples of silica are seen in the well known precious stones, the ruby and the sapphire. Potash, the remaining ingredient of mica, is familiar to everybody, and is extensively used in the arts. Our commercial supplies of potash chiefly come from the ashes of plants and trees, and their roots take it from the ground, the granite rocks being the original source. Granite is composed of quartz, feldspar and mica."—*Scientific American.*

Mica is very plentiful in Ceylon, but, as far as our observation goes, not in large sheets or in a tenacious form. Most of what we have seen has been in a crumbly state. When going round the new Nuwara Eliya drive to the right of the Barracks Plain about three years ago, we saw a large collection of pieces, of pretty good size some of them, glancing in the sun. We need scarcely tell our readers that the more felspar and mica abound in our gneiss the richer are they in potash, and, if pieces of such rock could be cheaply broken and pounded, a valuable application to the soil would be at hand. Is plumbago still used in Ceylon mixed with oil or grease as a lubricant for machinery ? We were told in Melbourne, that it was too heating. Mica, notwithstanding the silica in its composition, may give less friction. In an elaborate article we read recently on lubricating oils, the preference was given to sperm, but mineral oils were said to answer well. It it curious that mica should be used as an ingredient in two such opposite substances as cement and stiach gloss. Our readers are aware that the *kirimetti* of the Sinhalese —kaolin, China clay or pipe clay—is the result of decomposed felspar, and that the substance crystallizes into moonstone ; while alumina, in other words clay, is the source of the precious stones, which, according as they are coloured, are called rubies or sapphires. It is by a slip of the pen, we fancy that the writer in the "Scientific American" mentions those gems as the most elegant and the purest forms of silica. He had previously and correctly represented silica as known in its purest and most beautiful form as rock crystal. Rubies and sapphires are crystallized clay. Judging by appearance, we should suppose that asbestos, which resists fire even better than plumbago or mica, must have some affinity to the latter, only that asbestos seems to have no tendency to decompose. Asbestos is mineralogically described as "a variety of hornblende and pyroxene," occurring in long delicate fibres or fibrous masses.

THE CEYLON TEA ENTERPRIZE.

It may be, looking at the averages obtained in the Indian tea districts in India, that the estimates of probable returns :—700 lb. of tea per acre for low estates and 400 lb. for those at high altitudes (4,000 feet and upwards)—were over-sanguine. We know, in regard to other cultures, how insect and fungus pests and abnormal weather may disappoint even the most cautious estimates. On the other hand the damp, hot forcing climate of Ceylon must be taken into account. India is a continent and most of the tea produced there is grown outside the tropics—about 27° north. Ceylon is an island, with a climate of combined heat and damp and the region in which tea is being cultivated ranges about 7° only from the equator. The conditions for luxuriant vegetation could scarcely be better. The estimates of the Indian Tea Planter, therefore, may not be so "reckless" as the writer who appropriates nearly a sixth of the alphabet when denouncing extravaganee, may imagine. We cannot say whether or not our correspondent "Cha" had any particular estates in view when he condemned the sending of rubbish into the market. He certainly did not name any. The reputation of Looleconderа is fully established but nothing could be less germane to D. W. F. L.'s argument than, the high prices obtained for tea from this high estate. Until the art of tea-making is thoroughly understood everywhere in Ceylon, comparisons are not only odious but utterly valueless as settling the question of the respective merits of low-grown and high grown tea. We have seen and tasted tea of excellent quality grown a few feet above sea-level, while "rubbish" has been turned out on high estates" and *vice versa*. The question hitherto has been simply one of preparation. But taking into account not only the theoretical belief in the influence of high altitude on flavour, but also the now long-continued experience of Darjiling, and the Kangra Valley, there can be no doubt that the Indian tea planter was perfectly justified in anticipating that, when tea is equally well made on high estates and low, the more delicate flavour of the high-grown leaf will bring compensation in the market for the considerably smaller yield when compared with that obtained on low estates.

TEA IN CEYLON.

1st November 1882.

DEAR SIR,—"Cha"'s letter in your issue of the 30th ultimo, and your leading article on it, will, doubtless, attract a great deal of attention at the present time. His liberal, if not reckless, estimates of quantity of tea per acre and value per lb. might, no doubt, do good by inducing capitalists to embark their money in tea, but they will do much more harm than good by disappointing those capitalists if they are not fulfilled.

I think "Cha" would have done much more good had he given us facts and figures of the past year's returns on the places under his management, than indulge in what is popularly known as "gas."

Can "Cha" explain the low prices obtained for Dunedin and Ruanwella tea, at a recent sale, very much under 1s 5d per lb. all round, and those estates are also under an "experienced Indian tea-planter."

So far as could be made out from newspaper reports, which are all an outsider can learn from, unless "Cha" comes forward with facts, the average price was about 1s 0½d on the former estate compared with about 1s 4¼d for Loolcondera tea in the same paper, and this does not bear out what he says.

Does "Cha" include Loolcondera tea in the rubbish sent from old estates, as, so far as could be made out from newspaper reports, this considerably topped the market last year when "Cha" has been among us. "Cha" says that high estates will give higher prices to make up for deficiency of yield; how then does he explain that low estates as K. A. W. (one of the estates condemned by him for not having a full name on the chests) and Culloden, both low estates, especially the latter, almost at sea-level have given such high averages for their bulk teas viz. 1s 3d to 1s 4d per lb.

I have every faith in small but sure profits from tea and own land well suited for its cultivation in several districts, and it is with *a desire* to get further information of a reliable character that this missive is penned, and for this information the public in general will be grateful to "Cha."—Yours faithfully,

D. W. F. L.

THE CEYLON REGION FOR CROWN BARKS.

CINCHONA CULTIVATION IN AND AROUND NUWARA ELIYA.—A recent visitor to Nuwara Eliya and Kandapolla reports that he was much pleased with the appearance of some cinchonas on the Nuwara Eliya plains; and towards Kandapolla: "Portswood" estate and "Lover's Leap" still hold their places as officinalis estates in prime form and although both estates average 3 years, and some parts are 4 years old and over, the patches or vacancies are not more numerous than I recollect in coffee, and the trees are well grown and healthy. The system adopted at "Portswood" between two and three years since of cutting out small lots in the forest, well protected from wind, has proved a perfect success, but of course to attain this you must also have soil and lay of land, in both of which nature has highly favored this place and some others in the same locality. In the small blocks referred to, the officinalis trees are so thick that you can only with difficulty get through the plantations. "Court Lodge" is looking up well, and the new clearings belonging to "Pedroe" estate, which are on either side of the road between the 3rd and 4th mile posts from Nuwara Eliya in the direction of Udapussellawa are simply splendid. It might be expected after the three months of heavy rains we have had that cinchona officinalis would have made a very different appearance from that I saw. This part of the island is no doubt the place for officinalis, the group of estates all round in Kandapolla—wherever attention has been paid to planting, draining, and supplying—indicate this.

SALT FOR FISH CURING.

The very interesting letter to the *Madras Mail* which we copy on page 484, written by the chief officer of the Salt Department in the Madras Presidency, shews that on the opposite continent attempts to adulterate or "de-naturalize" the important condiment and antiseptic, sodium chloride, popularly salt, have been no more successful than those instituted in Ceylon. The use of salt in coffee and other hill-cultures does not seem to be strongly indicated, unless as a remedy against fungi and insect pests. Most of the salt obtainable here is from the admixture of magnesium chloride with the sodium, highly deliquescent, and it is not from deficient but excessive moisture that our hill culture generally suffers. But it seems certain that the extensive coconut palm culture of Ceylon, especially in the drier regions of our coasts, might be largely benefited by the application of salt, provided the substance could be so defiled as to render its recovery and use for food purposes impossible. The question has been frequently agitated, and on the last occasion a decided opinion was obtained from so high an authority as the late Dr. Lankester, that perfect and final adulteration was possible by means of admixture with salt of a substance exceedingly repulsive to most human beings, except to the Chinese who store it carefully even in their dwellings in order to be used as manure. Dr. Charsley, who was then Principal Civil Medical Officer of Ceylon, shewed, however, that the result of treating the horrible mixture with charcoal filters was to recover the salt crystals in a perfectly pure state. So long, therefore, as the necessity exists for a revenue from salt (just as opposed to Western ideas as the grain tax, but both equally necessary in the present conditions of life and government), so long, we fear, it will be impossible to obtain salt in Ceylon for agricultural purposes, except at the monopoly price. It is just possible that some of the many bye-products of the formations and manufacture could be rendered available under certain precautions. For purposes of mere experiment, in operations directed against fungi and grubs, we cannot doubt that Government would furnish our correspondent "J. S." with a few tons of salt at cost price, on the guarantee of personal honour that care would be taken to restrict the use of such salt to the experiments alone. One of the bye products of salt manufacture is magnesium sulphate or "Epsom salts." This substance might, perhaps, be supplied by Government at a low price or admitted free of duty for use in the anti-fungus warfare? We mentioned some years ago that in Cooke's book on smut rust, blight, etc., this was the only substance mentioned as a remedy against fungi. To the use of salt in agriculture we may recur but at present our object is to attract attention to the liberal policy adopted by the Madras Government as described by Mr. Bliss, in supplying salt at cost price (£1 to £2 per ton), for fish curing. Surely the Government of Ceylon might see their way to make similar relaxations under similar conditions? At present, we have ascertained there is no concession even in favour of fishermen, and probably the difficulty here would be that fish cured by means of duty free salt would be, none of it exported, but all go into local consumption. It would so, free of duty, go into com-

petition with and perhaps supersede the large quantity of imported fish, on which a tax is levied avowedly for the purpose of protecting the revenue from salt. Salt fish is, with rice, the staple food of a large portion of the people of Ceylon, especially the immigrant coolies; and it is obvious that the more salt fish is eaten the less salt in a separate state will be purchased and used. But we should think considerations of this kind would be put aside if there was really the prospect of fostering a new and profitable industry amongst a poor and hardworking race of men—the fishermen of Ceylon. At present they *somehow*, do cure a certain quantity of fish probably by means of salt mud or salt sand. It stands to reason that fish treated with impure salt is likely to become putrid and unwholesome, and leprosy as well as elephantiasis have been traced to the use of putrid fish as food. We are glad to notice that the Madras Government, while making liberal concessions as to the use of pure salt, have stopped this source of danger, and similar concessions on the part of the Ceylon Government might be accompanied with corresponding restrictions. The result would naturally be salt fish of a better quality and at cheaper prices than can now be obtained. Of course if the Government of Ceylon followed the example of the Government of Madras by establishing fish-curing compounds, the first experiments would be tried in proximity to the natural formations at Hambantota in the south of the island; Tondemanaar in the extreme north; and near Puttalam on the north-west shore, where "bay salt" is extensively manufactured in evaporating beds. All the fish caught within a good distance of Colombo, Galle and other centres of population, will, of course, find a ready market in its fresh state, the passenger-steamers now crowding to Colombo, helping to swell the demand. But there are extensive sweeps of coast, indented with bays and estuaries, in the east, north and south of the island, in which fish must swarm, for which no near market is available. For instance, on both sides of Battiealoa, especially round by Mulletivoe to Point Pedro; on both sides of Manaar; in the Gulf of Calpentyn, &c. The question is: are our fishermen enterprizing enough to take advantage of the proposed concessions if Government made them? As our readers are aware, the existine fisheries are carried on not merely by the Sinhalesg in the outriggered canoes and ballams, but by Tamils from the opposite Continent in their primitive rafts called catamarams—the simplest floats on which human beings can trust themselves on the waters of the great deep. They seem as safe as even the outriggered canoes, which we regard as not only models of beauty and swift sailers, but as excellent life-boats. We recollect the time, some thirty years ago, when the catamaram men first came over to compete with the Sinhalese in the fisheries of our coast. Great was the indignation of the local fishermen and great their surprize that the local Government would not accede to their petitions to drive away the interlopers from what they regarded as their hereditary preserves. The proper policy was adopted of leaving a pursuit on which a large portion of the people are dependent for most of their food, open and free; and now if the Sinhalese fishermen should be backward, the Tamils may step in and shew them the way to catch and cure fish on a large scale. And is it not possible that a joint-stock Fishery Company supported by European capital and guided by European energy, might be formed and successfully worked? It is considerably more than forty years ago since we made a similar suggestion through the *Observer*—when Governor Stewart Mackenzie abolished the fish tax, in truth. During a residence of forty-five years in Ceylon, which has just been rounded off, the writer has been a pretty close observer of the doings and appliances of the fishermen. But it is only within the past month that we have *noticed* the plan of fishing adopted by the catamaram men of having a *tender* attached to the raft which carries the net. We saw five Tamils—stout, well-formed men—preparing to "go a-fishing" from near the Kollupitiya railway station. There were six separate logs lying on the beach. Of these, four were first lashed together and the net placed on the completed structure. The three men told off for her then navigated the raft cleverly through the reef and the surf; the two men left behind, meantime lashing the two logs, embarking on this narrow raft and following the larger one, evidently in order to pull out and deposit the net in the sea and help to haul it in again. Is this system of fishing new, or is it merely that we have only now observed it? We shall be glad to hear from any who knows, on this and the general question.

THE BAMBOO DISTRICT OF COORG, INDIA.

"BROAD GAUGE" writes:—"The little province of Coorg, girdled byhills, and washed by a thousand streams, for a longtime little known outside the Presidency, is fast pushing itself into a promiuence which bids fair to give it first rank amougst the planting districts of India. A belt of forest immediately inside the ghaut range, varying from ten to fifteen miles in breadth, and traversing the country its extreme length, gives an area of some 250,000 acres. Within these limits the soil and climate are admirably adapted for the growth of coffee and cinchona. Only some 25,000 acres, or a tenth of the land available, are at present in cultivation. In this favored district, commonly called 'the bamboo,' the coffee is kept in a high state of cultivation, and planters are content with nothing less than an average yield of 7 cwts. per acre. Cinchona cultivation has not made much advance, but now that its adaptability for the more hilly parts of this belt has been ascertained, it is expected the enterprise will take a new departure. It is an absolute fact that one can ride for twenty miles through an unbroken sheet of coffee, no single field of which, at the present moment, can truly be characterised as in a neglected condition. Can this be said of any other coffee district in India or Ceylon? This Eldorado of coffee planters, possessing a genial climate, a teeming soil, and an abundant labor supply is not without its drawbacks. A remedy for these might be found, where the *Mail*, which is now the recognised mouth-piece of Southern India, to lift up its powerful voice in behalf of those enterprising men who have devoted all their energies and the best part of their lives to bring about the state of thiogs described. The first and chief requirements is improved means of communication. A railway is wanted, good roads are wanted, and a bridge over the Cauvery at Sidapore. This latter work was projected some years ago, and the Chief Commissioner, on his last visit pledged himself toset it in train, but so far nothing has been done. For six months in the year the roads are practically blocked for wheeled traffic, and in the dry whether they contrast more unfavourably with the smooth, well-kept roads intersecting the planting districts of Ceylon. But a railway would develop the country more than all the rest. The route from Tellicherry *via* the Baripolli valley and over the Ghats at Kootiyal, where the depression is greatest, and thence through an easy rolling country into Mysore, would tap extensive forests rich in latent resources, and convert in a few years the present 5,0000 tons export into 50,000 tons of coffee, not to mention other products such as chinchona, rubber, cocoa and rice. The present executive show unwonted liberality, and are ever ready to recommend any policy that would pro-

mote the material wealth of the country, But their hands are tied, and all measures of reform are subordinated to imperial exigencies. From the published reports it will be seen that the revenues of Coorg are far and away over the expenditure. A considerable portion of the revenue has hitherto been devoted to the upkeep of a Native Regiment at Mercara. It is settled however that Mercara shall be no longer a military station, and it is to be hoped that future budget allotments will show the money thus saved has been diverted to the due maintenance and extension of local public works.—*Madras Mail.*

SALT FOR FISH-CURING.

(To the Editor of the "Madras Mail.")

SIR,—A letter appeared in your issue of the 12th inst. upon the subject of fish-curing, which shows that some at least of the public are ill-informed as to the system on which salt is now, and in future will be, issued duty-free for use for this purpose. I shall therefore be obliged if you will allow me the use of your columns to explain it. Financial considerations necessitate the imposition in this country of a duty on salt many times in excess of its value. Its price, thus enhanced, is an effective bar to its use, as in other countries, for manure or for the many industrial purposes to which it is applicable. The question how it can be so adulterated, or as the technical term is, "denaturalized," as to admit of its duty-free issue for such purposes, without danger to the revenue from its diversion therefrom to alimentary uses, is one which has long engaged the attention of Government, but hitherto without result, as no effective method of de-naturalization has yet been discovered. For fish-curing, however, this is not necessary. The conditions of the industry are such that it can without practical inconvenience be carried on in guarded enclosures which correspond to the bonded warehouses of the Customs Department, and under the supervision of the officers of Government, who are responsible that the untaxed salt there used is not allowed to pass out for ordinary consumption. For several years past, therefore, salt has been issued for this purpose and in this manner at selected localities on the coast, at prices which have varied from six to twelve annas per maund, and which have been calculated on the basis of covering expenses only, the cost of manufacturing or purchasing the salt included. These prices are equivalent (at par) to from £1 to £2 per ton, and have until recently, owing to the small scale of the operations, involved a loss to the Government, the margin added to the prime cost of the salt having been insufficient to meet the charges on account of buildings, establishments, &c., The quantity of salt used to cure each pound of fresh fish is somewhat less than a quarter of a pound, but the fresh fish loses weight in the process of curing to an extent which varies according to the weather, the kind of fish, and the system of curing. An estimate of the loss at fifty per cent, will however, be an extreme one, so far as I am informed. The cost of the maximum quantity of salt required to cure a pound of fish may therefore be taken as ranging from ·44 of a pie to double that sum.

The quantity of fish cured in the official year ending on the 31st of last March in the eleven fish-curing yards then existing aggregate 1734 tons, an increase of close on 400 tons as compared with the preceding year. Quantities of food stated in tons, however, convey but a vague impression to most people. I may therefore say that these 1734 tons were probably sufficient to furnish a meal apiece to over eleven millions of persons, or considerably more than one third of the population of the Presidency.

Up to the beginning of April last, when (Madras) Act I of 1882 came into force, it was not illegal to use for fish-curing the salt-earth which effloresces in abundance almost everywhere along the coast and in many places in the interior, and which frequently contains more than fifty per cent of pure salt. Large additional quantities of fish used to be cured in this way, though in so imperfect a manner as to be probably an unwholesome food, and certainly most offensive to the European sense of smell. No statistical information is available for the framing of an estimate of the addition, though of indifferent quality, thus made to the food supply of the people. This use of salt-earth was, however, so systematically abused, and offered such facilities for the manufacture of contraband salt, that in the interest of the revenue it was found necessary to prohibit it. To prevent, as far as possible, this necessary measure from pressing hardly on the fishermen, who are a poor class, it has been determined to develop the fish-curing yard system, which has hitherto been in a somewhat experimental stage, and to open new yards in sufficient numbers for every fishing village along the coast to have one within a few miles. In pursuance of this policy, arrangements have been made within the last six months for the opening of more than eighty new fish-curing yards in addition to the former eleven. This number will be further increased if experience shows that a demand exists for additional accommodation of the sort. It has also been suggested that if facilities are offered for the duty-free issue of salt for the curing of fish in private establishments persons may be found willing to invest capital and to embark in the business of taking and curing fish on a large scale. Companies formed with this object are successful in Europe and, so far as I can judge, should succeed in India also. The supply of fish is most abundant and unfailing. But more scientific means than the catamaram and the hook and line are required to gather in from the sea the harvest which nature provides. Steam trawlers pay on the English Coast and should do so on the coast of this Presidency, if worked with economy. To buy and work them, or to organize the native methods of capture on a scale large enough for economical and efficient curing, capital is needed; and capitalists will probably object to conduct their curing operations otherwise than on their own premises. Nor, in fact, could they do so; for the accommodation afforded in the Government fish-curing yards is insufficient for any but the petty operations of the native fishermen, and it would not be consistent with the position of Government, nor in all probability, profitable to the industry, that it should undertake to erect buildings, &c., suitable to the conduct of larger enterprises. Government may do much to foster infant industries, but experience proves that the less they interfere with established ones the better. It was on these considerations that the advertisement alluded to by your correspondent was issued. If capitalists should embark on the business of fish-curing, Government will be willing to aid them by the duty-free issue of salt at the lowest possible price consistent with the realization by the Department of a fair manufacturing profit, and on some such conditions as that suitable and secure premises be provided for the custody of the salt and for the conduct of the operations of fish-curing; and that the adventurers pay for the deputation of a Government officer to supervise the work and prevent the removal of the salt otherwise than in corporation with the salted fish, and give such other security as may be thought necessary that the privilege granted them will not be abused. I shall always be happy to afford enquires on the subject any information in my power if they will call at my office in Madras.

H. W. BLISS,
Salem, 24th Oct. Comis. of Salt Revenue.

THE NORTHERN TERRITORY OF SOUTH AUSTRALIA

Where Messrs. Poett and Mackinnon have "located" themselves in "Rum Jungle," is thus noticed in a recent paper:—

Messrs. Erickson, Cloppenburg, Harris and Head, who have taken up land on the peninsula, in small blocks, are all doing well with sugar-cane, tobacco, maize and other produce. Their cane is splendid in size and quality, and there is some hope of their being able to obtain a small mill, as they are rather far from the De Lissa Company's mill. The above men have been the real pioneers of tropical agriculture in

the territory. The only capital they started on was a stout heart and a strong hand. Some samples of the cane growing on the Daly have been brought by Mr. Owston to Palmerston; they are quite as fine as any in the Government garden, and there twenty acres similar on the plantation, ready for nursery purposes this year. The maize from the Daily is also first-class, and the cobs much larger than any hitherto grown here. It now remains to test the land on the Adelaide for sugar growing; and there, although the topsoil is very rich, the subsoil of clay seems to frighten intending planters. In my last report I quoted from Dalton's "British Guiana," to show that such subsoil is good for sugar, and I now supplement by quoting from "The Coolie," by Mr. Jenkins, the author of "Ginx's Baby," and who was sent out at the same time as the commission ordered by Earl Granville, then Secretary of State for the Colonies. Mr. Jenkins made a most minute inspection of the sugar lands in British Guiana, and there, where the finest sugar is grown, he reports the subsoil as "like the London blue clay." Another fault found with our alluvial soil on the river banks is the excessive quantity of water, and therefore people say "it is only fit for rice." Now the Chinese at Mindale, one mile from Palmerston, have been trying patches of sugar-cane on some low swampy land, and the result is fine cane, long and thick, the density of which has not yet been tried. This cane may be said to have grown on land never dry; and in this climate, where there are four or five months without a drop of rain, I venture to state that the moist land will be the most productive. At the Palms the soil is very moist, and the result is a thick close crop. The largest canes on the De Lissa estate are those on the moister land, near the creek. A number of Chinese propose to start a rice farm, but their application did not come in until after the lands were withdrawn from sale. Work is progressing at Messrs. Poett and Mackinnon's at Rum Jungle.—*Mackay Standard.*

BIG CINCHONA TREES AND THEIR SHAVINGS.—LOWER DIKOYA, 25th October:—There are a few old cinchona succirubra trees on Wattawella Estate, age I believe unknown, which can easily beat Udapussellawa. The wet shavings from one of these trees weighed 40 lb. I guess there are few who could duplicate this!

AN AGRICULTURAL DEPARTMENT FOR MADRAS.—We understand that the Secretary of State has given his sanction to the establishment of an Agricultural Department for the Madras Presidency. Speaking at the Saidapet farm in December last, when the new Agricultural College buildings were opened, Mr. Grant Duff remarked that the Government of India had been marked by many phases, and that at last we had entered on the agricultural phase—a phase which concerned 75 per cent. of the population of this Presidency. He trusted that the South India peasant would soon become as anxious about the three F's as his peasant brother was in Ireland, only that the F's in this part of the world would stand for fuel trees, fruit trees, and fodder crops. The all-important question now is, who will be appointed to the charge of the agricultural Department, which, we hope, will not be a mere office for the collection of statistics, but an institution based on the model of the American agricultural Bureau. No man has done more for scientific agriculture in India than Mr. Robertson, and it is hardly posible the Madras Government can overlook his claims to be the head of the agricultural Department.—*Madras Mail.*

CINCHONA SHAVINGS FROM MONSTER TREES.—I fancy Mr. Mais of Mahapahagalla Estate, Badulla, can top your Uda-Pusselawa correspondent, and if Mr. Morice could be induced to shave one of his giants I would not be surprised if he had nearly double the quantity reported by your correspondent. The big trees beat anything that I have seen. Ask Mr. Morice to tell you about them mself—PASSARA.

COFFEE AND TYPHOID FEVER.—Dr. Guillasse, of the French Navy, reports that in the early stages of typhoid fever coffee is almost a specific. Two or three table spoonsfuls of strong black coffee every two hours, alternating with one or two tea spoonsful of claret or Burgundy wine, produce a most beneficial effect. Citrate of magnesia daily, and after a while quinine, is the treatment followed successfully by Dr. Guillasse. —*Madras Mail.*

AGRICULTURAL EXPERIMENTS.—Major Walker proposes to entrust the experiments with Ipecacuanha. *Hevea Brasiliensis* and *Chinchona Calisaya* in the Silent Valley to private enterprize, subject to inspection and report by the officers of his Department. The Government "have no objection to this course and their acknowledgments are due to Mr. Ferguson for his proferred assistance. The proposed experiments at Manantoddy with Hevea and Ipecacuanha and at the various elevations named by the Conservator with *Chinchona Calisaya*, are also approved. The results should be carefully noted and reported. The rubber plant might also be tried at or in the neighbourhood of Courtallam, the exceptional climate of which has proved favorable in some cases to plants and trees which will not grow elsewhere in the Presidency. The Conservator should, however, try at his discretion any likely localities, reporting the result to Government."—*Madras Mail.*

APHDES (PLANT LICE) ON TEA.—A Mercantile Firm in Colombo has addressed us as follows:—"We send you per bearer a few sprigs of tea covered with some insect, regarding which our superintendent writes as follows:—'The whole clearing is affected with it and I am not able to take in the flush. I shall feel much obliged if you will kindly send same to the Editor of the *Observer* and find out what it is, and if there is any remedy for it. I believe it is owing to the very wet weather we have been having for the past two weeks, as I did not notice it before. Strange to say, it only confines itself to very tender leaves.' We shall be glad to have any information you can give on the subject." We referred the affected tea to our entomological referee whose report is:—

"The tea has been attacked by aphides, hundreds of which I found at the bottom of the box containing the tea sprigs. They suck the sap of the plant and being such delicate insects, of course prefer the very tender leaves. The pests can be kept down in hot-houses at home and where there are not many plants to deal with, by inexpensive treatment, but when a whole tea clearing is in question, the most inexpensive treatment would probably not pay. They little white things on the leaves are merely the cast skins of the aphides." There can be little question that the superintendent is right in tracing the attack to the effect of persistent wet, and if, with a return of dry weather the pest does not disappear, a resort to pruning may be necessary. Sulphur is one of the best remedies, or sulphur and lime, but if the area affected is large, we suppose that beyond pruning and burning the prunings, little can be done except to "watch and wait," as we do in regard to coffee leaf-disease. In our own experience we have found a small nocturnal moth the greatest enemy of tea. This is the first occasion, and we trust it may be the last, in which we are compelled to take cognizance of plant lice amongst the enemies of our new and promising industry.

Correspondence.

To the Editor of the Ceylon Observer.

CINCHONA CULTURE.

IMPORTANT INFORMARTION: SHAVING CINCHONA SUCCIRUBRA TREES; COVERING THE SAME AND THE HARVESTING OF RENEWED BARK.

Kirkoswald Estate, Bogawantalawa, 24th Oct. 1882.

DEAR SIR,—Following is the result of some of the experiments made by me, with the object of ascertaining the age at which succirubra trees should be shaved; what benefit results from covering, and how renewed bark ought to be harvested.

The analyses are by Messrs. Rucker and Bencraft, Loudon. On remarking on sample D. they say:—"It is a mistake sending it in the form of quills, this applies to all renewed barks; the much prized *druggists' quill* must be original bark. All renewed barks go entirely by analysis, and not merely appearance."

Referring to A. B. and C. they say: "Please note cinchonidine is very rich; this sometimes is a great advantage, sometimes of less moment. Now, however, this alkaloid is in good demand, and therefore your barks, if offered today (23rd June R. A), would reap the full advantage."

Six shillings sounds very good for renewed red bark, four months' growth, off trees only 5½ years old. It is hard to account for the superiority of the four months' renewal over that of twelve months' from an older tree:—

CEYLON AND JAMAICA COFFEES COMPARED.

Bellevue, St. Andrew, Jamaica, Sept. 16th, 1882.

SIR,—In that most valuable journal, the *Tropical Agriculturist*, under the heading of "Sales of Ceylon Coffee at Good Prices," I find a letter signed by P. D. Millie, in which, after quoting the prices of Ceylon coffee (the highest of which is 113s) he says:—"E. I. T. states that the prices he gives will shew that Ceylon coffee can hold its own against the world. I will go further than this. I say that our fine Ceylon coffees can beat any other; produce it where they may." I had little idea that the prices obtained for fine Jamaica coffee were so little known, and I have much pleasure in sending you what is a complete refutation that the "Ceylon coffee can beat any other; produce it, &c." I have before me now the priced catalogue of coffees sold in Liverpool for 1881-82 crop by Messrs. Brancker, Boswell & Co. I may mention this is not an exceptional year; we have been having *long* prices for some *years*, and never under 128s for best brands for the last 20:—

Sales 31st March 1882.—S E W R 120s; 132s; 140s. R A M 173s.
Sales April 14th 1882.—R H C M 125s; 139s; 140s. R A M 130s; 136s; 140s. C A M L 129s. C V C M L 115s; 122s.
Sales 9th May 1882.—R H G M 137s; 138s. [AML] 130s; 135s.
Sales 23rd June 1882.—SF WR 127s; 140s; 140s 6d; 141s. R A M 132s; 140s; 142s. R H C M 110s; 143s 6d. W H 120. A C L 125s. C A M L 125s; 116s.
Sales 14th July 1882.—R A M 100s. R H C M 135s; 147s.
Sales 11th August 1882.—CV CML 117s; 122s. PH CMG 120s; 132s; 136s; 136s. ACL 120s. RH CM 140s; 147s; 146s; 141s. RAM 112s. SF WR 130s; 140s. WH 124s.

I could give numerous other sales at really fine prices, but have preferred, both for the sake of brevity and argument, to send you these as above. The prices for coffee are always interesting to the planter, and I have no doubt Messrs. Brancker, Boswell & Co., Exchange Alley, Liverpool, would, if requested, send you a priced catalogue, which would be very interesting to your numerous readers.—I am, sir, your obedient servant, JOHN DAVIDSON.

[Can the Liverpool market be considered a fair test? Exceptional prices for certain good marks can always be pointed to; and we have never denied the great value of Jamaica's finest "Blue Mountain" coffee only beaten by "Cannon's Mysore." Here is the scale in the London Price Currents:—Ceylon plantation from 52s to 106s; Jamaica 36s to 110s; East India 54s to 114s; Mocha 100s to 122s.—ED.]

MOISTURE FOR COFFEE.

Coppah, India, 17th October 1882.

DEAR SIR,—I notice a letter in your paper of the 29th August by "P. T. L." in which he says moisture is required for coffee, which I quite agree with.

Here we have to retain sufficient moisture for five or six months, but, if we drained our coffee, as they do in Ceylon, we should be dried up before our next rains came round; but we dig our ground over at least once a year to the depth of 9 in. to a foot, after the heavy rains; so that the ground is again settled and yet soft by the time the next monsoon sets in. This digging not only retains moisture in the ground but also allows the air to come in contact with the earth below the surface and to improve it.

When I first came here from Ceylon I was hot upon having drains, but I now think them a farce.—J. R. E.

[It is obvious that in Mysore, with six months of drought, different principles of culture may succeed to those adopted in a country like this, where, for several years back, coffee has suffered from excess of moisture.—ED.]

A WORD FOR GUMS, CEYLON.

Gampola, 25th October.

DEAR SIR,—Has any one seen the leaf disease on *young* trees or on *topped* trees which have retained their original characteristic blue foliage? If young and topped trees escape the disease, gums will no doubt continue to be largely planted as breakwinds. Grevilleas might take their place were it not that the seed is scarce and expensive, even in Australia. The black wattle is infested with parasites. Casuarinas are troublesome to raise, as poochies destroy the seedlings and are not of much use as breakwinds (a great many were planted last year on Vellakande, which are not growing at all rapidly). On the whole, perhaps, we cannot improve on the blue gum as a breakwind.—Yours faithfully, T. H. S.

WHAT AILS OUR COFFEE TREES? "W." IN REPLY.

SIR,—In reply to your correspondent "L," who asks if I can cite instances where orchards, or large gooseberry gardens have revived after a series of years of unproductiveness, I may say that I do know

of such cases: of one in particular where a large orchard comprising several kinds of fruit-trees and gooseberry bushes, growing in a soil of extraordinary richness, had become almost barren of fruit, though retaining a luxuriant growth; but as their fruitfulness was restored by the simple use of the knife, I do not regard the evidence so afforded as applicable to our case, except in so far as it proves infertility to be compatible with unimpaired powers of vegetation.

I would remind "W. D. B." of the very large crop referred to in a former letter as following immediately on the very worst attack of leaf-disease I have ever witnessed on a large scale. As mentioned in that letter, the attack culminated in the month of February, and on the 18th of that month the trees were a sad spectacle of leaflessness. The area affected was of some hundreds of acres. I cited the fact originally, and now refer to it again merely *as a fact* bearing on the present discussion.

The "probable analogy" suggested by your correspondent "J. S." would, even as a conjecture, have considerable weight, coming from so practical and experienced a planter; but it is in the nature of things untenable. There is a cardinal difference between the modes of attack of the two fungi: *Hemileia* obtains access to the leaf tissue by means of the stomata only. It requires an open door to effect an entry. *Peronospora*, on the other hand, wants no door, but breaks through the wall, the cuticle. Now, as there are no stomata on the *roots*, the *Hemileia cannot* attack them; whilst the *peronospora* has a free range over all the succulent surfaces of its victim! Again as the attack of *Hemileia* is confined to the leaves, the tree and all the rest of its organism is perfectly free from disease when they fall. But the mycelium of *Peronospora* can retain its vitality in the dried substance of the tuber, and spring into destructive activity whenever this begins to grow. It sends forth its pernicious shoots through the new organism, destroying both stem and leaf of the young plant.

Where will "J. S." now find his probable analogy? Could the essential difference between the attacks of the two fungi be *over-estimated*?

It is very gratifying to me to see that the subject I have commended so earnestly to the attention of my fellow-planters is at length being noticed. If only they would contribute, and tabulate *facts*, we could not *fail* to acquire valuable knowledge, even though we might not arrive at a full solution of the mystery. Even conjectures, however, are better than nothing; especially when suggested by men whose minds are imbued with facts. True science is but a sound, logical generalisation of *facts*; but then they must *be* facts; and the deductions therefrom must be logical; and not merely plausible. W.

DETERIORATION OF NATIVE MYSORE COFFEE.

Tellichery, 26th Oct. 1882.

DEAR SIR,—Referring to your remarks in your issue of the 10th current on what we say regarding native Mysore coffee in our letter accompanying our export statement for the past season, the following will explain why it is that "deterioration" in quality should take place in consequence of the introduction of Coorg plants. The word "deterioration", however, is not that used by us, and, although what we said might be taken as signifying the same thing, it is not exactly the idea intended to be conveyed. Those who know the produce will know what was meant.

Until a few years ago all the coffee grown in the Mysore districts, namely, Munzerabad and Nuggur, was from what is known as the Munzerabad plant, and the produce was noted for its fine qualities, the plantation ranking next, as much of it still does, to Mocha. The native sort has also been highly valued, especially in France, where it generally obtained 8s to 10s per cwt. more than other Indian native coffee. As an instance, as high as 64s to 65s cost and freight to Marseilles has been paid during the past season for this quality.

The trees from which this produce has been long obtained have for some years past rapidly declined in productiveness, the plant having evidently begun to fail in vigor, insomuch that, on supplying vacancies, it was found the supply rarely came on. On the other hand, the Coorg plant, especially that from Nalknad seed, grew readily, and European planters went in for replacing their failing Munzerabad trees with Coorg, which seem to find a congenial soil, where the other had sickened and died. This has gone on extensively of late years, and native growers are also planting up their lands with what they find to be a much more productive tree, though the quality of the produce is not considered so good. The change of quality is now beginning to be observed in the French markets, the beans from the Coorg plants being observable amongst the old Mysore produce. It is consequently not so highly valued, and, as Coorg plants gradually replace the old Munzerabad, so we fear it must, to quote from our letter, "gradually alter the character of this produce."

With reference to our statement, where native is not distinguished we have not been supplied with separate returns for these ports, but we believe the qualities may be taken as chiefly consisting of plantation.

Regarding the Indian crops not shewing any serious falling-off, although several districts have suffered from leaf-disease and other causes, this in great measure arises from the extension of cultivation in other parts. True, North Wynaad has now become almost a wilderness of abandoned plantations and in South Wynaad too, many properties, especially on and near the Ghauts, have relapsed into jungle, and this also applies to the forest land of Coorg, but in the Bamboo division of that district great extension has of late years taken place as well as in the Nuggur district of Mysore.

Part of the Coorg coffee finds its way to Madras, although it has to travel some 300 miles against 50 to 60 to this coast, and altogether some 1,200 to 1,500 tons of plantation coffee must have gone to that port, so that this quantity would fall to be added to our returns as representing the export of Southern India.—We are, dear sir, yours faithfully,

ALSTONS & Co.

[Our readers will feel greatly indebted to Messrs. Alstons & Co. for the interesting and useful information they have supplied. It is an important fact that coffee from introduced seed, should flourish where plants had previously sickened and died. The fact seems to shew that the soil has not been deprived of its fertilizing properties, and we submit that good hope may be entertained that as the new trees advance in age their produce may more and more resemble the old and famous Mysore coffee.—ED.]

QUERIES ANENT COFFEE CULTURE.

Colombo, 27th Oct.

DEAR SIR,—1.—I have been reading "W." 's letter on "What Ails Our Coffee Trees?" with much expectancy, and in his last but one I observe that he refers to a matter which has been occupying my own attention for some years past, and I believe that of many others, viz, when is the proper time to prune, and what is the immediate and more obvious effect of this operation on the trees. He also refers to the idea of "wintering," or, as it might, perhaps, be called with equal propriety here "summering" our coffee trees.

2.—I should gather from "W."'s remarks that he is in favor of early pruning, which term I think is generally understood to mean immediately after crop, *i. e.*, for the majority of estates from the beginning of January and on to the end of March.

3.—"W." says the hot weather of this time, combined, as I understand him, *with the pruning*, has a tendency to check growth. "W. D. B." and he seem also to be agreed on this point.

4.—I presume they are both alluding to the same kind of pruning, *i. e.*, branch pruning; and the question I should like to see answered authoritatively is this: Does the pruning away of branch and foliage check growth in any other sense than that it deprives the tree of what was in process of growth? I do not of course refer to the pruning away of *dead* wood.

5.—I grant that the first effect of pruning may be to throw back and concentrate the sap *after the* wounds caused by the pruning are healed; but it has always appeared to me that the first visible effect of the operation is the effort of the tree to replace the wood and foliage of which pruning deprives it in a new and more vigorous form.

6.—The new wood thus formed, however, cannot be expected to be capable of maturing fruit within 6 months afterwards at the least, and therefore, unless the pruning has the effect, besides stimulating the growth of new wood, favourably to influence the contemporaneous formation of blossoms, it cannot be looked on as a means of enhancing the crop to be looked for from those blossoms.

7.—Then comes the further question: how does the effort to form new wood and foliage affect the formation of blossoms?

8.—If the season at this time is wet the effect of pruning is immediately visible in the formation of new foliage, and planters are wont to say "that blossoms are gone to leaf." They say it is "the abnormal weather." The effect of the pruning seems now to be questioned.

9.—In a dry season there *is* usually a greater show of blossoms; but surely pruning is not to be credited with the effect of weather, and even after a dry season one hears it said "my blossoms were equal to 10 cwt an acre, but I only gathered 4, and yet my pruning was all finished by the middle of March!"

10.—Now in olden days—in the days of short labour supply—I should like to know how many men had finished their pruning by the middle of March, compared with the number that were well contented if they could get round by the end of June or even July, and yet we are accustomed to look back to those times regretfully as the times when our trees produced so much crop that we had not the labor to gather it!

11.—Is branch pruning an operation that should be carried on at the time that our trees are preparing to blossom?

12.—Root pruning is another matter, and I must leave that for another letter.—I am, dear sir, yours faithfully, L. M. S.

COFFEE FUNGUS: THE AILMENT AND THE REMEDY.

27th Oct. 1882.

SIR,—As held by "W.," coffee leaf-disease and the infertility of the tree are separate existences;* they, acting in ominous concord, have issued in the present collapse of the general prosperity. Such mysterious visitations cannot be maledictions of creative power, and their advent are not nowadays accepted with the abnegation of man's reason. A search for cause is prudent, such often leading to the discovery that the presence of a misfortune is conditional, and indicative of some powerful, though common but combatable, deficiencies, and are recurrent under like conditions, but often unrecognizable, when affected by a change of agency. Our misfortune may have happened from some such cause, and, if recognized, it may permit of an alleviation of our hardships being made, while proving a useful and effective lesson to planters of all products, and an encouragement against despondency and stimulant to both Government and people, to set about a hopeful but assiduous resuscitation of prosperity, concomitant with arboriculture, the natural industry of the island, and referable principally to its moist and steady climate. The exposed planting of fruiting trees especially, is proper, by which method is obtained the fullest effects of elemental power, but from the first it requires a constant conservating care of the soil to effect its being a thriving and entailable occupation of a population. Annual plants, if not sufficiently productive one season, can in due time be replaced by others, which encouraged by better tillage will grow more vigorously. But with perennial vegetation spasmodic cultivation does induce enfeeblement.

The revival of general prosperity will not be expected from the mere planting-up of decaying coffee lands with new products, nor will any permanency be effected without the principles of enforestation being adopted, nor will it be wholly brought about by the lucky selection of a few inches of fertile mould, made by enterprizing planters of new products amongst our crags and peaks. Great success in opposing the denuding effects of the weather, and in combating the gradual absorption of the materials of growth from the soil, has been attained to, but permanency is not now calculated on by Europeans, whose natural interest is in making the best of the soil speedily, to enable them to return to their own homes with more money, if possible, than they brought with them into this, the land of their sojourn. And nothing better can be done with the retired mountain sides than to turn them into hastened use, exercising as much conservative care of the soil as increasing knowledge will shew is profitable.

An inquiry into the causes producing the present depression cannot be too late, whilst population is leaving our shore, while a once flourishing revenue lies low or tea and cocoa grow. But let apathy rule and twenty years hence, when the fertile mould now around new products, will lie atop of the once little cared for coffee soil, now alas! in the hollows of the deep, poverty-induced parasites of strange growths will, without searching back through the book of Fate, afford a sufficient subject for contemplation to the studious cryptogamist and reduced planter of these days. It would therefore be better to learn the lesson now, and, while stately products are young, dreams of marbled halls may be more safely indulged in. But yet like the careful watch at sea, snooze with the weather-eye open.

Plants have their troubles too, but while no sigh of the weary comes from our stunted fields of coffee and though these pictures of want may be less attractive than the outlines of animals done on the same scale, a general precept from experience has been learned over again, that the profits yielded by lean cattle and leaner pigs are no less sure than short crops from starved trees.

No practicable method can keep up an estate on hilly land to its original power, and to a former general belief in the permanency of open forcing planting, on such ground, must be ascribed much of our trouble. No planting without being enfostered can protect itself, especially on steep slopes, and Governor

* "Not proven": what is obvious is that the infertility of the tree is mainly the consequence of a pest which by constant attacks on the lungs of the tree disorders and debilitates its whole system and functions.—ED.

Gregory told us that, which information at the time we took rather unkindly. It is supposed His Excellency's opinion was that we were not much more practically intelligent than those Irish planters who let in the blight so shockingly upon their taters. There are estates on which long-continued, careful and regular cultivation is found to pay. In the villages, much of the once good old coffee yet lingers, yielding a miserable return for its cumbrous occupation of such advantageous ground as surrounds the hamlets. Few, if any, new products will thrive sufficiently fast if planted under shade on stiff trampled-down ground and destined to try a struggle for food against the contesting surface roots of old and powerful trees. A half of the existing coffee is so far recoverable, but the balance must be replaced and supplied. For village cultivation, coffee as yet is the most suitable tree, from its natural habits, its long-tried powers of life and proved value of its product. Successful example is the best precept, and by Government alone against the present despondency can a practicable and permanent system of cultivation be introduced and speedily spread among the people who are not slow to learn or imitate a success.

All openly planted products, on unterraced hills or on undrained, untilled lands, must sooner or later, from the experiences learned in coffee-planting, prove amenable to like unpropitious conditions. Early experiment and close observation will discover many necessary improvements, and, if in practice the cost cannot be accepted, at least the warning to look out for consequences has been timely effected.

The present flourish of green leaf and new wood to those who have it, if sustained, bespeaks the blessing of another crop, but the eventualities of the dry season from December to May and later on the burden of crop following, will as in late years bear hard upon the reserve of strength, now so small and so seldom added to, to soil or tree.

Parasites of all societies, however useful in the great balance of power, gifted to reproductive creation, with the turn of the scale in their favor, are with limitations generally obnoxious and inclined to exceed their orders. *Hemeleia* is of this breed and its attacks must be hostile to the health of tree and leaf. The fleeting changes in the leaf are the outward tokens of the condition of the tree, and the fall of the leaf, while a natural incident distracts attention from the circumstance that premature as well as matured leaves fall by adventitious agencies this is best observable on trees which are known to be enfeebled. The exigencies of cultivation shew that trees with early retillage will not drop their leaves so rapidly, as those beyond the point where retillage has been put in abeyance. From trees under regular cultivation a great fall of leaf, although it may not be immediately of serious import, yet tells of slackening root action. A loss of young wood by atrophy often accompanies an enfeebled state of the tree, resulting from delayed re-cultivation. The heavy fall of leaf about crop time it is admitted is so far natural, but it is not all a necessity, for retillage and manure applied two or three months before crop very much reduces the loss of foliage and the shock generally given to the trees at that period.

Notwithstanding an occasional fig-up, the present one being the longest on record and generally complained of, the coffee yearly retrogrades. The sensitive leaf and young branch, being the periodical evolvement of the existing power of the tree, it may be reasonably assumed that its appointed time and strength is in some, if not in full, proportion to the enfeebled condition of its origin, and its own reduced power when under fungal attack. Leaves, strong and dark green, will remain attached for months, especially on plants, with their elaborating surfaces much destroyed and affected, thus giving but a maimed help to the tree. This reduced assistance from one leaf, multiplied by the many affected, reasons of considerable mischief done to the tree.

Last year's continued wet, following upon the effects of crop, benumbed the roots, kept the ground soaked and cold, thoroughly blighting numbers of trees and denuding them of leaf and twig, making recovery very slow. The little crop this year is in the warmer localities, on tilled, light and stoney or open land.

Cutting back of the roots to increase fertility is a practice in advanced arboriculture necessary occasionally with old trees. It necessitates a deal of collateral expense to be a successful operation. Digging among the roots and stirring in mould and manures, yearly if possible is preferable, and this is generally accompanied with a considerable cutting of the roots. A light cutting off far-stretching roots is very beneficial: the rootlets are increased and renewed and their combined action is the mainspring of tree-life. When cultivation is applied to backward fruit and coffee trees, the fruit, besides increase of quantity, increases in size and quality. Yearly manure halved bi-annually applied is found to save fruit, branch and leaf from withering, especially on light land. Continued experiment, it is to be hoped, will show it to be profitable as well. For upon that question, will it? hangs the expenditure to be made and the system to be adopted in the cultivation of any product. The stirring of the soil necessary in the application of a bulky manure and the recovering of any exposed roots in advent of the dry weather, prevents any serious attack of the disease, but no tree but one dead need be expected to be completely or constantly free from the yellow spot, but as in domestic economy, an occasional hunt, and a periodical comb down reduces to bearable limits the discomforts of parasitical abundance, in like manner does cultivation given to the coffee tree act towards the fatal fungus, but so far as the two coffees are concerned the yellow fungus is a new and attractive addition to the beauties in creation.

Strong trees in the open, often together in patches, must from analogy have their roots in good feeding and well subdrained ground. These and such trees as are kept in good condition by culture, also those which are in genial shade and good soil, just so long as the favoring conditions exist, are not much troubled by disease, nor do their leaves fall so often suddenly as happens from trees less propitiously situated.

Contact of diseased trees or attempted inoculation and other like means fail satisfactorily to put leaf-disease upon vigorously growing trees; yet the yellow spot will be found to come apparently without cause in time. Even there however, cause may yet be found. Soil, which, being naturally light, made more so by periodical forking, and being charged with an yearly accumulating mould, from manure applied, causes a rapid growth of rootlets to the surface. The earth being mounded around the tree to cover the manure, is easily drained of superficial moisture, and farther dried by the action of the rootlets will in continued dry weather induce a severe attack of disease; yet this does not taogibly affect the flower or crop, provided the drought is not too long continued.

Dryness at the root, aided often by an earth bound condition there, is the leading agency reacting on the leaves which induces leaf-disease. The opposite extreme of stagnated wet and a stiff soil has a like effect, but except in the last two years—though previously to a limited extent on flats—wet has had less influence. There are years which are wetter than others, the difference not being such as to attract general attention. Then the native coffee under thick shade, in hollows and on flats, drop their leaves in

such numbers as to cause the impression that the trees are decaying fast ; the unnatural excess of fall is called leaf-disease, although little fungus can be seen. The ruling condition where leaf-disease prevails is a parched or repressed condition of the roots, and oftentimes of the lower roots only, which even in shewery weather, towards the close, or after the monsoon, will be often found to underlie a deceiving cover of wetted soil, which supplies the leaves and top roots only with the lacking moisture. It is only heavy, continued, or repeated showers, which get through a stiff or hardened soil down to the nether roots. In these times of the year, both upper and lower roots are liable to dryness, and, in ratio to the nature of the subsoil, the protection or not, by mould and the foliage of the tree even a salutary influence must be effected by moisture given off by adjacent forest. To the severe effects of these recurring seasons in dry districts, upon coffee in thin and worn-out soil, is due much of the abandonment which took place before disease was known. During dry weather, as is known, new land and free or tilled soil afford immediate access to the roots to rain and dew and with little waste.

On the fine old estates which still keep to the front, it is not to be expected that the trees generally can now bear as they did—they are aged, and their circumstances of growth are much reduced. The forest forming these estates was carefully and fortunately selected. For many years the soil continued free, deep, and rich. The multitudinously grown rootlets felt no restraint below, nor repression above from loss of mould and the thinning shade of a failing tree. Subdrainage was well effected in the free and unconsolidated earth through chink and channel left by root and worm. Reservation of moisture was sufficiently preserved by the mould and the free soil, assisted by decaying roots and timber. Food was everywhere and was for years supplemented by the mouldering remains of heavy forest. In highly cultivated gardens alone could such propitious conditions for growth be artificially effected and trees there would be twice or thrice renewed within the time those patriarchal trees have stood.

The remedies for the repression of coffee leaf-disease and against infertility will in time prove useful to other products. The remedies can happily be applied as one ; and it is: attention to the roots, encourage and sustain the growth and the renewal of the rootlets, by keeping the soil free, by supply of food, and the regulation of moisture.

Experiments and observations on a few trees or on a field will test these assertions and they are not new from me. R.

WHAT AILS OUR COFFEE TREES? ANSWER: LEAF-DISEASE.

30th October 1882.

DEAR SIR,—"W.," in his second letter, tells us that the sole object of his first was to prove that *hemileia* was not the primary cause of the universal decline of the fruit-bearing powers of our coffee trees ; his demonstration really taking the form of the enthymeme :—(1) Coffee was cultivated for years without attracting the disease ; (2) an unhealthy constitutional condition is a *sine qua non* for the establishing of a fungoid growth in any organism ; (3) leaf-disease did establish itself in our coffee ; therefore, our coffee was in an unhealthy state prior to the attack of *hemileia*.

This logical conclusion must, however, be condemned as blind, empirical, and haphazard, being directly opposed to that arrived at by Marshall Ward after long and careful study. He proved beyond a doubt that "a spore, taken from a diseased leaf and sown on the lower surface of a *healthy* coffee leaf in a drop of water, germinates."

Let us pretend to ignore for a moment this judgment of the cryptogamist, and see how far "W." has made out his case on his own hypothesis. Accepting this, if we critically analyse the word "primary," giving to it its two senses of priority of time and place, there will hardly be any of us so bold as to deny that on the first count "W." has proved his case. But, sir, where shall we stop if we attempt to unravel the mystery of the first cause of leaf-disease's existence! Surely "W." is arguing on false premises when he tells us (letter No. 7) that it is ridiculous to suppose the leaves and permanent structures of our trees have any interdependence.

The leaf we all know to be one of the conservative organs of a tree, and (if a temporary one) is as absolutely necessary to the growth and preservation thereof while it remains on it, as lungs to an animal. It seems to me as unreasonable to suppose that a diseased leaf will elaborate naturally pure juices for the system of its parent tree, as that humanity can touch pitch with impunity or that jelly filtered through a bag saturated with kerosine oil will turn out a palatable condiment.

In previous letters I have ventilated my belief in an existing analogy between the two kingdoms, animal and vegetable. This I maintain in the face of "W."'s dogmatic assertion that the theory of a vegetable circulation is absurd. It would, therefore, be the basest apostacy on my part were I to allow his inference (that the leaf is not as necessary to the tree, as any member or membrane to the human entity) to pass unnoticed. Though a cabbage may not be able to apply the moral, the sense of the fable of the "belly and the members" bears equally on its constitution and a king's. Still harping on this analogy, let me adduce a case which seems to me to parallel poor coffee's present state. Last crop a coolie (male), in the prime of life, met with an accident which necessitated the amputation of a leg. him Shortly after his return from hospital, his wife left for a younger, whole man. * * * Leaf-disease has amputated poor coffee's leg, and he can do next to nothing in the way of reproduction, and may be expected before very long to hobble off the "hooks."

The 3rd para of the 7th letter savours strongly of *suppressio veri*. Though the disease does not enter through its roots, as "W." there declared, he omitted to add that it is quite possible that the whole tree may be affected by a vitiated elaboration of the sap in the leaves. I do not hold with "W."'s fears that, even if we expelled the disease, it would be bound to return, nor do I think for a moment that our coffee would still remain unproductive if such a crusade were successfully carried out. It is interesting at this stage to recall Dr. Trimen's ideas conveyed in his covering letter to Marshall Ward's 3rd report. "We know," he wrote, "that there is one sufficient cause of leaf-disease, the uredospore of *H. V.*, that is produced only by a previous one, and can germinate only in moisture. This then is a *vera causa*, and in accordance with the wellknown medical aphorism, to remove this would be the true practice." There is no pursuit of phantoms or first causes suggested here, but a measure which only our increasing poverty renders daily more and more impracticable to us, the entire destruction of the accursed spores. Why cannot "W." accept this doctrine with that faith he exhibits as to the unexplained existence of the first cause of all these minor first causes?

In his first letter "W," by way of pointing out the harmlessness of leaf-disease, tells us of a group of estates that gave satisfactory crops in 1876 although just before the blossoming time these estates were nearly leafless. It is a moot point in my mind whether leaves are of such importance to the tree at the period of blossoming—when the tree's energies go to the

developing of flower-buds, and its wood-formation receives a check from the dry weather—as later when it has to collect all its forces for the maturing of fruit. Unless I am much mistaken, most of our English orchard trees put forth their flowers before a single leaf is formed!

Then 'W' opines that in 1876 the fungus attained its utmost force. He seems so *positive* of this that I dare not contradict it. Nevertheless I fear that just now we have on us an *utmoster* attack than that was.

It is not so long since the ravages of the pest paid us two distinct visits in the year; now we have *hemileia*, like the poor, always with us. I have allowed this letter to run to too great a length, and will now bring it to a conclusion. I am persuaded that *leaf-disease* is the prime cause of our present misery, and that its ravages would have been a mere trifle to what they have been, but for *wind*, which in its turn would have affected us but little, had more prudence been exercised in the *clearing of forest land*; that *grub* has slain its thousands of trees, but that with *carelessness in selecting plants*, and a host of other causes which have been adduced, have moved merely as satellites to *Hemileia Vastatrix*.—Faithfully yours,

P. T. L.

WHAT AILS OUR COFFEE:—STARVATION?

SIR,—"W." in his letters, tried to show us, "what ails our coffee" he has shown us it is not leaf-disease and has not shown us anything more. Starvation is what ails our coffee; either 1st no manure, 2nd manure mis-applied, or 3rd insufficiency of manure. 1st perhaps it will be asked, how did coffee bear in former years without manure? In former years coffee got well manured with decayed weeds, in proof of which, I will give two instances. 1st:—Palamcotta estate in Bakwana, belonged to a Colombo merchant; it was very weedy, then the merchant failed and nothing was done to the estate for some months, it was bought by Messrs. C. Shand & Co. and immediately sold to Messrs. Mitchell & Rust, when they got the place the coffee could not be seen for the weeds, and yet that place gave 15 cwt. an acre after that for 3 years running. Next was Oonagalla estate in Kornegalle, said to be 120 acres in extent but, what with slab rock, etc., I do not believe there was 80 acres of coffee. It was allowed to get into such a mess that coolies had to be put on with catties to cut down the jungle stuff before any weeding could be done, and yet that place gave 3,000 bushels of parchment for some years after. About 1864 an idea was started that we could not grow weeds and coffee; it sounded very well in theory, but I think proved a failure in practice and there is no doubt that the sun takes more goodness out of the soil, than the weeds did. 2nd.—Like in weeding a new fashion has been started in manuring, and that is sowing it broadcast, and then forking it in; to fork it in thoroughly it would require more than one forking, which is seldom done; the consequence is, that a portion of the manure is washed away, and the question is, do the roots of the coffee get at the remaining manure to be of any benefit. I doubt if the coffee derives much more benefit from it, than what a mere forking would have done. If crops are expected from manure, the manure must be placed where the roots can get at it.

3rd. Insufficiency of manure. Baron Liebig said, "that a coffee tree would take up 1 lb of bone duts to produce a crop," but when it had taken up the 1 lb of bone dust, what has a tree to go on with, to mature that crop and carry it on to the next? Is it any wonder then that if a tree takes up what little manure that has been applied, it is unable to bring its crop to maturity and is left more dead than alive. Much has been written against coffee of late, but, it must be remembered that we have had instances of individual trees under peculiar circumstances bearing at the rate from 5 to 30 tons an acre, and with proper cultivation there is no doubt that coffee can be made to bear as much as it ever did before. I do not say that with proper cultivation there may not be occasional failures of crops. Over those circumstances man has no control, and coffee is not the only product that suffers from those circumstances. What I say is this, that with proper cultivation coffee is the most profitable product that can be grown in Ceylon.—I remain, yours truly,

G. F. HALLILEY.

[By "proper cultivation" we take Mr. Halliley to mean liberal manuring and little, if any, weeding. Where are trees to be found bearing at the rate of 30 *tons* an acre?—ED.]

COFFEE LEAF-DISEASE DUE TO VITIATED SAP?

DEAR SIR,—Trees (exogenous) of which our coffee is one, never die a natural death; they die from accident or disease: either the roots go down into an unsuitable strata, or all the available food within their reach has been exhausted, or the roots get so matted that they prevent the sap flowing up into the tree, or some disease sets in; so that, if a tree got sufficient food and moisture and met with no accident, it would go on growing and bearing for ever. If a tree takes up too much moisture without sufficient essential food, as soon as a little bright, sunny weather sets in, the sap gets disorganized and mildew or some other disease sets in. Before a coffee tree gets an attack of leaf-disease, the edges of the leaves turn a dirty yellowish white and the wider it becomes the worse that tree is attacked with leaf-disease, so that there cannot be any doubt but that the sap is first disorganized and it afterwards contracts the disease through some action of the atmosphere on the leaves; or how are we to account for patches away from any disease suddenly getting affected? There have been trees free from disease though surrounded with affected trees. It is a pity the observers did not examine, the condition of their positions. I have no doubt that they would have found that they were growing in better soil than their neighbours. As they were not trees not liable to be affected, their seed planted elsewhere get diseased. Another proof that leaf-disease is owing to the disorganization of the sap is what first drew our attention to the disease and that was that our fruit was attacked, in the large number of black beans, in the crop of 1870-71. So that the only cure for leaf-disease is proper manure, properly applied, and then proper treatment of the trees and we would get proper crops; without this, we can no more make coffee pay than a London market gardener could make his garden pay, if he did not cultivate it properly.—Yours truly,

G. F. HALLILEY.

P.S.—There used to be a tree on "Baharundrah" estate in Kotmalie that used to give its 5 and 6 bushels of cherry. G. F. H.

THE TEA-PLANTING ENTERPRIZE IN CEYLON.

November 6th, 1882.

DEAR SIR,—Let us take "D. W. F. L."'s first paragraph in which he considers "Cha"'s estimate of yield per acre of tea as "liberal and reckless.' Tea planters in Ceylon have not, as a rule, been anxious to publish their annual yield per acre, but, if we may take as our standard the statement published in the *Observer* by Messrs. Mackwood & Co., namely that the yield at Gallebodde estate for the year ending June 30th 1882 (when the tea was four years old) was 530 lb. per acre it does not strike one that

"Cha" was being reckless in stating that lowcountry estates might be worked up to 700 lb per acre.

"D. W. F. L" is lucky in having such a scape-goat to refer to as Loolcondura, but is he sure that the various estates he mentions are shipping all the tea they make, from broken pekoe to rough leaf, or are some of them keeping back their *rubbish* to sell locally and to raise in consequence their home average.

While allowing that "D. W. F. L." is perfectly correct in saying "that two year old crop may be doubled or even quadrupled by natural increase in growth during the following year," I should like to know whether "D. W. F. L." puts it down to the circumstance mentioned above, or to superior management that a tea estate rising three years old, more than doubled its monthly outturn of dry tea three months after it had been taken in hand by "an experienced Indian tea planter."

I beg to offer my congratulations to "D. W. F. L." on his being the lucky proprietor of tea land in various districts: at the same time should he meditate opening up for this product, I fancy that, unless he moderates his caustic mode of inquiry, he will remain as ignorant as he now professes to be, of the cultivation and manufacture of tea.—I am, &c., TAY-ELAY.

VINE CULTURE AND ELEPHANTS IN THE TIME OF THE DUTCH IN CEYLON.

Colombo, Nov. 8th 1882.

DEAR SIR,—That the Dutch were not the first to introduce the vine into Ceylon is evident from the following translation from Valentyne's History of the East Indies. Vol. V. under the heading "Ceylon." The writer is describing a visit in 1602 to the Court of the King of Kandy by Commander Spilbergen, the first Dutchman who landed in Ceylon. The journey was from Batticaloa near Bintenne:—

"Nearing Kandy, the King sent gilded palanquins and elephants with gorgeous trappings to meet the party, also constant supplies of fruit and of wine,* equal in quality to any procured from Portugal, the produce of a vine which the King himself had planted."

Speaking of elephants, the same writer goes on to describe the elephants of Ceylon as far superior in sagacity to those of the neighbouring continent: "Not only did they at the word of command salaam their visitor, but when their riders were anxious to mount on to their backs, the elephants, at a given signal, saved them all further trouble by taking them up in their trunks and safely depositing them there!!!" —Yours faithfully,

WEEDS IN COFFEE CULTIVATION.

To the Editor of the "Madras Mail."

SIR,—Your correspondent "Ghirkee Hooloo" says about weeds, "If kept low and thin they do not do much harm." The advocates of the system so well described by "Grass Knife" go further and maintain that weeds and grass not only do no harm, but are actually beneficial, to say nothing of the indirect advantages of having your best labour, available at the right time, for that most important work, handling. Should further proof be necessary, after Mr. Harman's letter, "Ghirkee Hooloo" could not wish for a better illustration of the conservative effects on the soil, of this system of cultivation, than the way the supplies have come on in the old coffee "that showed unmistakeable signs of the effects of 'Ghirkee Hooloo.'" Some other cause must, I think, be looked for, to account for what your correspondent said. When you have this grass you must dig deeper, as is done in the valley, and thus a further benefit is indirectly forced upon you. Dubbe Hooloo is the worst enemy of this kind of cultivation. I have known its roots grow straight through the tap roots of coffee, and estates destroyed by this grass. There is nothing left but to dig it entirely out. The advocates for clean weeding will allow nothing in favor of the system, but fall back on the good quality of the soil in the valley to account for the condition of the coffee and say, wait! They forget that many of the estates in the valley are thirty years old, and to judge by the vigour of the trees now, one would rather be inclined to think that a great deal of the soil had been improved by the system. For deterioration has certainly not yet set in.

Wynaad. A CONVERT OF THE KINGS.

* Could this possibly be the juice of the coconut?—ED.

TEA SIEVING MACHINES.

(From the *Indian Tea Gazette.*)

SIR,—Would any of your subsribers kindly inform me whether they have tried an ordinary sieving and winnowing machine such as is used in farms at home in England. The largest siever and winnower by, say, Messrs. Ransomes, Head and Jaffries of Ipswich, costs about £11 in London, and may cost R170 to be landed at any steamer station in Cachar or Assam. Mr. Jones of Fenchurch Street manufactures one of the same type under the designation of Taxidinemeter, and sells it for three times the price, viz., £30. If anybody has worked an ordinary winnower, would he let me know from actual trials what length of time it took him to sieve 4 maunds of bulk tea through Nos. 13, 10, and 8 mesh wire sieve; and how many maunds of pekoe or B. P. could be winnowed in an hour? Mine is a small garden, yielding about 600 mds. of tea a year. So I cannot think of purchasing Ansell's machine, which has been introduced in this neighbourhood, and is very well spoken of by those who have seen it working. HANSTIE.

WEEDING COFFEE ESTATES.

(*To the Editor of the "Madras Mail."*)

SIR,—At present on many weedy places where they can afford to weed monthly, it costs as much as R2 per acre per mensem. This is in itself sufficiently ruinous, but if by this weeding we are really burning the candle at both ends, the matter is of serious importance. Replies to the following questions would be thankfully received, and I trust brother planters who have gained their experience in other parts will kindly come to our help.

I.—Is it recommended that no weeding whatever should be carried on during the S. W. monsoon months, *i. e.*, June, July, August and September, except cutting down the large ones?

II.—How about grass? There is a small creeping grass here, which it is impossible to eradicate when once it gets into the ground.

III.—When should digging be begun, and to what depth &c., should the soil be dug? Should it be turned over or merely loosened up? And of course as much care as possible should be taken not to injure the main roots.

IV.—What would the cost of digging where men are paid 4½ annas per diem?

V.—What sort of digger is used?

VI.—Where the weeding can be done for 12 annas or a rupee an acre per mensem all the year round, would any of your correspondents prefer to allow the place to get weedy in order to reap the benefits of digging in weeds?

Trevandrum. A TRAVANCORE PLANTER.

COPRA IN FIJI.—The Fiji *Times* states:—In 1881 the export of copra exceeded that of the previous year by 193 tons, although, in consequence of a decrease in value, the amount realized for the larger quantity fell short by £22,737 15s 10d of that representing the receipts for the smaller export.

CINCHONA PLANTERS ought to take hearts of grace over the splendid prices obtained today by Messrs. Robinsoo & Dunlop for the Waverly and Holmwood Crown Bark from 6-year old trees: R3·55 and R2·10 per lb. are equal to 6s 9d and 4s 3d in the home market, and they shew that good bark will sell as well locally as in London.

PRESERVED BANANAS.—A new method of preserving bananas has been patented in Jamaica, and although its results have not yet been subjected to a commercial test sufficient to form the basis of a decided judgment, we may say that there is at any rate a fair prospect of a new and important industry being thus opened up. A sample of the fruit prepared nearly twelve months ago is now before us in excellent condition, and retaining its flavour in a remarkable degree. We are not acquainted with the details of the process, but it is evident that the fresh ripe fruit has been cut in half lengthways, and subjected to some method of slow drying, which has prevented fermentation and decay. It is believed that 7d or 8d per lb. would be paid for the fruit by manufacturers of wine; and that it would also command a sale amongst the general public for culinary purposes.—*Planters' Gazette.*

"CINCHONA BARK ALLOWANCES" which were so frequently complained of by the planters as running away with a large proportion of their consignments, abolished accordiug to the telegram which Messrs. Rucker and Beneraft have been good enough to send us—all but the "tare." We should suppose this to be a concession of importance, because if we mistake not occassionally planters pointed out that from 15 to 20 per cent. was swallowed up in this way. Of course the object in abolishing is to attract bark to the London market. But if a marcantile friend is correct, the allowances abolished are of less consequence than was generally supposed and any meterial change in the trade rather improbable. He writes :—

I have been looking at some account sales of cinchona :—

S. Q.—No. 1...5 bales gr. wt. 1,060 lb.
Tare 24 lb.
Draft 10 ,,
Dust 30¾ ,,
Tret 38¼ ,, 103 ,,

Nett wt...957 lb.

S. Q.—No. 2...9 pack. gr. wt. 1,694 lb.
Tare 235 lb.
Draft 18 ,,
Dust 43¾ ,,
Tret 53¼ ,, 350 ,,

Nett wt...1,344 lb.

No. 3... gr. 3,249 lb.
Dust and tret 210 ,,

3,039 lb.

The allowances, draft, dust and tret come to about 7 per cent. But *is* the *dust*, an allowance abolished? it is roughly 3 per cent. Leaving out the dust, the other allowances abolished would be about 4 per cent. Opinions are divided abont the effects of this measure I think it will after a time end in the reduction of prices in London to the extent of allowances abolished. Another authority writes :—The London Brokers, seeing the bark trade going past them, and going to the Continent, have come to their senses. If there ever was a mistake it was in fleecing the poor bark-grower, but it has done some good, for it has assisted him to sell locally and so has opened up a good continental trade perhaps more quickly than would otherwise have beenthe ease.

THE "T. A."—From Messrs. Haddon and Co. we have received some numbers of the *Tropical Agriculturist* for naturalists and planters, published at Colombo, at the office of the *Ceylon Observer*. Vol. 1 appears to contain a variety of useful articles on the cultivation of the cinchona, the introduction of Liberian coffee into Ceylon, the tea-plantations of India, and similar topics.—*Graphic.*

ABNORMAL COFFEE BERRIET.—Mr. Dewar of Roseneath, Kandy, writes to us :—"I send you a sample of curious coffee, which grows at 'Anniewatte.' There is only one tree of it, and year after year it goes on bearing this abnormal bean, and that alone." The cherry is certainly curious—not larger than ordinary *Coffea Arabica*, but it is flattish and split open with 4 or 5 small beans instead of two forming. Has Mr. Dewar ever attracted the attention of Dr. Thwaites or Dr. Trimen to the tree or berries? The latter, we feel sure, will be interested in seeing the cherries and the tree. How does it stand leaf-disease?

COMMENCEMENT OF TEA CULTIVATION IN INDIA AND CEYLON.—The following may be accepted as the dates on which tea cultivation commenced in the different districts :—

Assam...	...	...	1835
Kumaon...	...	...	1850
Cachar...	...	...	1855
Dehra Doon...	...	...	1855
Sylhet...	...	...	1857
Kangra...	...	...	1858
Darjeeling...	...	...	1860
Tera ...	...	...	1860
Chittagong...	...	...	1860
Neilgherries...	...	...	1862
Chota Nagpore...	...	...	1872
Dooar...	...	...	1875

These dates are from a London contemporary, and we believe are generally correct.—*Indigo Planters' Gazette.* [If by cultivation, growth in appreciable quantity is understood. In the case of the Neilgherries, for instance, a Mr. Rae sent us a specimen of tea grown and prepared by him, a dozen years before 1860, while the plant had been introduced many years earlier still. In Ceylon we date the regular cultivation of tea from 1867, but it is only since 1875 that special attention has been paid to the cultivation of the plant.—ED.]

MAIZE IN INDIA [AND CEYLON.]—Mr. Robertson, of the Saidapet Farm, reports very encouragingly of his experiments last year with maize, the seed of which he procured from Sydney, Australia. From a sowing of 80·5 lb. of seed, an outturn of 3,378 lb. of grain and 24,595 lb. of straw was obtained. Before sowing he tarred the seeds, to prevent them from being eaten by crows, squirrels or coolies; the decoction in which the seed was dipped being composed of one-and-half pints of hot water and one-fourth of an ollock of tar. He has been able to place about 2,500 lb. of maize seed at the disposal of Collectors for district experimental cultivation. Mr. Robertson writes :—"The maize crop is one worthy of much attention in this country. Without the aid of irrigation water, on the poor soils of the farm, good tillage and the moderate use of manure secured the production of an average outturn of 984 lb. of grain and 6,270 lb. of straw per acre; valuing the grain a, 30 lb. per one rupee, and the straw at RS per ton prices readily obtainable, the crop was worth R55-3-1 per acre, while the expenses incurred on tillage, manure and harvesting amounted to not more than R30 per acre." The straw of maize is also very rich in sugar, and from the jnice of crushed straw he obtained 3 per cent of jaggery. Mr. Robertson is surprized that maize has not yet received any attention in this country for the production of malt for use in brewing.—*Madras Mail.*

TEA AND CINCHONA CULTIVATION IN THE HILL-COUNTRY OF CEYLON.

LINDULA, Nov. 12th, 1882.

As seen from the railway train in passing, the cacao and Liberian coffee on "Liberia" estate looked flourishing and that the latter presented no external signs of leaf-disease. This fact was noted, because I had be told that *hemileia vastatrix* had latterly attacked the large leaved coffee with, if anything, *more* virulence than in the case of the Arabian species. No doubt if Liberian coffee is badly attacked, the idea of virulence will be exaggerated in proportion to the much greater surface of leaf covered with the brown and orange coloured sporangia. I may add that I have seldom seen the old species of coffee looking fresher or more free of disease : alas, however, that I should have to add, freer of crop. It is true, however, thatI have not been on Balmoral or any other of the exceptionally favoured coffee estates, where "the colour" (green, golden and ruby in succession) still shews. On a well-known estate in Kotmalie, which for nearly forty years of its existence yielded large and profitable crops, I noticed large patches of coffee bushes uprooted, to make room for cinchona plants and tea sown "at stake." I hope the experiment of placing the seeds *in situ* will be more successful than has been the case with a few put into holes here. Plants from seeds simultaneously sown in the nursery and then "planted out" are much more advanced, notwithstanding the shock of removal. On the Kotmalie estate referred to, was tried one of the first experiments with cinchona succirubra on worn-out coffee land. Accustomed for several years back in journeyings up and down to watch the progress of this grove of cinchona, it was a shock to me on this occasion to see the space vacant. I was told that the trees had been coppiced. It would be very interesting to know the pecuniary history of this experiment and also to learn the fate of the stools left in the ground. There was, of course, good grounds for preferring the coppicing process to the now popular one of scraping or shaving. Where the trees are vigorous and shew no sign of "dying off," all the arguments are in favour of this process. It can, it is now believed, be repeated within each twelve months, so that two harvestings of shavings can be obtained per annum for several, perhaps for many years, before the necessity for coppicing or uprooting arises. And as a well-known planter in this district has fully proved, each successive crop of bark after the first, is likely to be superior in quality to the first and to fetch correspondingly higher prices, in the ratio of 2s per lb. for original bark and 5s for renewed. This has been the result in the case of succirubra trees, subjected to the shaving process, and, as the robust hybrids or *cinchona robusta*, of the glabrous and pubescent forms, are likely to give even better returns, the question has been raised whether the time and expense necessary to raise pure Ledgers from the nursery or by grafting on succirubra stocks could not be better bestowed on the more vigorous kinds, if even their renewed barks are neither so thick nor so rich in alkaloids as is undoubtedly the case with the best forms of Calisaya Ledgeriana. The bark of both succirubra and robusta is pretty thick ; the matured trees being of large diameter, yield large quantities and after the first shaving the renewed bark will be rich in the most precious of the alkaloids,—quinine. The Ledgers are delicate, apt to suffer from climate and disease, while succirubra and in an eminent degree robusta, is vigorous and disease resisting. The wonderfully fresh look of the glabrous-foliaged robustas has especially struck me here, where calisayas, officinalis and in a lesser degree succiruhras have suffered from the disease which first appeared on the gum trees. The district is ringing with and rejoieing at the good fortune of the owner of "Waverley" estate, who is said to have realized about R8,000 from the bark of 3,200 or 3,500 trees. It would be interesting and useful to learn the age of the trees and whetherthey were coppiced, uprooted, or merely shaved Of the value of a forest of several hundreds of thousands of cinchonas, standing up amidst fields of coffee, I formed a vivid and high opinion when on the morning of the 10th I accompanied the laird of Mattekelle over a portion of his beautiful domain of plantations and swelling patenas. In the plantations are from 600,000 to 800,000 cinchonas, many of them well advanced, and if these resist disease and the twice-a-year shaving process, they will form a source of wealth far superior to the coffee which sheltered them when young and which now they are over-shadowing. Here for the first time I saw the shaving process applied systematically and extensively, and I was much struck with the improvement, since years ago, I assisted at some of the first experiments, made with Mr. Moens' method, which is now likely entirely to supersede poor MacIvor's stripping process. The shaving instrument, in the use of which the coolies are so expert that tree after tree is rapidly completed, is an adaptation of the carpenter's spoke shave, with an opening wide enough for the long shavings easily to slip through, and the knife so set that, with one operation, just the proper proportion of the epidermis and inner bark are removed, the wood being nowhere hared. From above downwards and from below upwards, the coolies seemed able to operate with equal ease, and a dozen or a score of trees can be shaved in the time in which one could be stripped. The shavings are more easily dried than the whole bark, and they can be pressed into bales of limited size, so as to save freight. Mr. Smith told us he was a convert to the process of covering the trees after shaving, not because of the effects of weather on the health of the trees, but because of the greater quantity and better quality of the bark obtained by covering. He uses the convenient patena grass, and he gave a good reason for preferring grass of some sort to tarred paper, or any other impervious substance, under which, action injurious to the bark and the tree might be set up. All kinds of substances are being tried, but whatever is adopted the process is pretty expensive. Has any one tried a felting of jute waste ? The Superintendent of Abbotsford has recently utilized the long stalks of gladioli which grow luxuriantly along the sides of paths. Strips of leaves of aloes, New Zealand flax, and many other plants could be turned to account. The great point is not to use string which passing coolies can steal. Plant-fibres will answer. We have heard of good success with strips of brown paper, tied on with coir fibres, single strand, but two or more knotted together. The shaving is a simple and inexpensive process. The expense is in the covering; yet it pays amply. But to go back a little. The effect of the recent fearfully abnormal south west monsoon—unusually windy as well as unusually wet—was painfully manifest in the appearance of the coffee on each side of the Dimbula Gap, especially on the Kotmalie side. No such effects of weather had been witnessed previously since "the forest primeval" had given place to coffee. Not only were the branches forced upwards, but the whole of the foliage, such as it was, left on the trees was small, shrivelled and of a pale yellow colour, just the colour which distinguishes a flush of best Assam hybrid tea. And this leads me to the fact that in its superior power of resisting wind, lies the superiority of tea to coffee, cinchonas and most other products. About a month ago a planter wrote that practically the whole of the cinchona plants put out were killed off by the chilly wet, and another gentleman calculates his losses of ledgers and robustas over a clearing of thirty acres as at least one-third of what he put out. This was from wind laden with wet. The contrast in the case of very extensive plantings of tea on Abbotsford this year is very striking, not one per

cent of the plants having failed to grow. This fact, as well as the growth made by one-year old plants, and the luxuriance of the older tea, excited the admiration of an experienced Indian tea planter who came especially to see the actual position of matters. His verdict was "Finer tea and a better tea soil there could not be." His admiration was shared by a couple of planters who were encouraged in their own operation of planting tea at a high elevation. Special plants allowed to grow as seed-bearers, which had attained heights of 10 feet to 24, were declared to equal anything seen in Assam, and one astonishing plant excelled everything the Indian planter had seen or heard of so greatly, that he said the dimensions, if published, would excite only incredulity. Nevertheless I venture to state just the facts. The tree which arrested and fixed the amazed attention of our visitor, grew by a path side at an elevation of 5,000 feet. It was not the tree-like stem or the *height* of the tea bush which astonished Mr. Cameron, but the vast area covered by its spreading branches. Let the diameter 16½ feet be trebled, and the circumference obtained is 49½ feet.

THE WEEDING AND PRUNING OF COFFEE.

A discussion on the necessity for clean weeding of plantations arises at regular intervals in our columns and the subject has been acquiring a new practical interest of late years, since scarcity of money has made it so difficult to maintain the usual works on estates. Our fear has always been that in the case of Ceylon our soil, being as a rule inferior to that of India, cannot bear both weeds and plants. There are experienced planters, however, who think differently—as witness Mr. G. F. Halliley and the writer who addresses us on page 497 from Doombera—one of the districts by the way, where a sufficient depth of good soil exists to justify an experiment in cultivation after the Indian fashion. In respect of pruning again, the Ceylon custom is called in question especially by Indian tea authorities who have visited our plantations and who find fault with "the waste of money in weeding and to some extent in pruning." Curiously enough, the minimum of pruning would appear to do for Liberian coffee; but in respect of the Arabian kind, the preponderance of opinion among local coffee planters of experience—more especially among those who have secured the best average crops—is that far too little attention as a rule is given to the comparatively expensive, but profitable work of timely pruning. What is the proper "time" is a question still asked, however, as witness a thoughtful letter in our columns a few weeks ago.

Meantime, we observe a feeling growing up among the younger generation of planters that their predecessors—the men of thirty years ago—did not pay sufficient attention to the teachings of experience, nor bring a proper amount of thoughtful consideration to bear on their work at a time when they had all the land before them where to choose, in virgin forest and rich soil for their coffee plants. It is well therefore to hear what one of the most thoughtful of planters who dates from a byegone generation has to say for himself and his fellows and although the following paper was written at our request, more than a year ago, it is fresh and applicable to the "Weeding" discussion recently started:—

"I observe, in the published opinions of certain planters of a new school, a reaction against the system of treating coffee, that has grown out of the experience of five-and-forty-years. Those fresh minds have evolved from their inner consciousness that Weeding and Pruning is a mistake, and in consequence that the planters of the past, were rather a poor lot—men without originality, or sound judgment, who merely dropped into a groove, and had not the pith to move out of it, or the readiness of resource to choose another course. These new hands, in laying their views before the public, only display their own ignorance of the history of Coffee Planting; else they would have known that there is hardly a possible theory, with regard to the treatment of coffee, that has not been tested, again and again. But even with ignorance of what has been done a little common sense would have led them to consider that the omission, of two, out of the three, most costly and exigent operations of coffee cultivation, was far too obvious a bit of economy to escape the notice of planters, who were economical by nature, or who were forced into economy by circumstances, or who had a theory to maintain. In point of fact, monthly Weeding was a system of very slow growth, and its economy was the chief quality that enabled it to make way: it was the least costly way of dealing with weeds, and that under which coffee continued most verdant and grew quickest. Had the modern revivers of old theories ever seen the effects on coffee, of cutting the weeds with reaping hooks, once or twice a year, as I have, they would probably have hesitated to commit themselves, and expose their ignorance of the subject they undertake to teach. As to Pruning again, there are two ways which have something in their favour, in various cases, and conditions. First, let the plant grow as nature wills it, cut nothing, and strip nothing, but take what nature sends, and be thankful. But if you would have a tree to yield the maximum crop on conveniently arranged wood, keep it down to a fixed height and remove all superfluous and worn-out wood. Coffee planting was ten years old in Ceylon before Pruning went further than keeping down suckers, and there are now perhaps planters of a dozen years' standing that never saw a tree on tolerable soil so treated for ten years. After the second crop, the whole growth of the tree goes into the two highest pairs of branches, which, dense and intricate, exclude light and air from all below. The lower branches gradually die and drop from the stem, and by the tenth year nothing else remains, and the wood is so matted and interlaced that one could walk without much discomfort on the top of a line of coffee. Thus, both the present system of Weeding and Pruning are the progressive teachings of experience, and fell on minds quite as acute and logical as any now coming into play."

THE COCOANUT TRADE OF TRINIDAD.

(From the *Oil and Paint Review*, Oct. 3rd.)

Trinidad, Sept. 4th, 1882.

The Island of Trinidad, British West Indies, has grown cocoanuts on the east coast since the last century, but on account of the difficulty of shipping the entire nuts they were all manufactured on the spot, and the oil and fibers (in bales) being less bulky, were shipped to Port of Spain chiefly for local consumption. Some of the fibers were exported to Barbadoes, and even to England. The exports of nuts dates not more than about 20 years back, as follows, the value being given in pounds sterling:

	Nuts.	Value.		Nuts.	Value.
1863	226,791	—	1878	4,241,270	£12,723
1865	419,752	—	1879	5,039,070	
1870	873,329	—	1880	4,227.276	14,193
1875	2,978,218	—	1881	over 6,000,000	20,000

Most of these nuts went to England as dunnage between sugar hogsheads, and lately as top cargoes in vessels carrying asphalt. They are shipped as

entire nuts, the husks being utilized in the manufacture of fibers for upholstering. Mattresses made with cocoanut fibers instead of horsehair and cotton do not harbour vermin. They sold in former years at a higher rate than horsehair mattresses, but since large quantities of cocoanut fibers have been produced the prices have fallen. As no cocoanut fiber works are as yet established in the United States, very few nuts (less than half a toillion) have been sent to New York and Philadelphia, and all the shippers who have sent entire nuts from here in the beginning of this year have lost money. The husking of cocoanuts is done here at from one dollar to $1.20 per thousand, whilst our exporters were charged in New York $10 per thousand, No entire nuts will henceforth be sent by Trinidad merchants to the United States.

There are still thousands of cocoanuts rotting on the east coast of Trinidad for want of shipping. They sell there at from eight to ten dollars per thousand. Husking there costs $1.20, so that the entire cost to the buyer does not exceed twelve dollars per thousand. Captains of small schooners (say of 100 to 120 tons register) could bring American provisions to Port of Spain, and then start for the east coast, fill their vessels with 150,000 or 200,000 peeled nuts, return to Port of Spain, and clear out for the United States. They could save the price of droghing (from six to seven dollars per thousand), and the transhipment from the island droghers to ships in Port of Spain. Vessels under every flag can load at any port of the island for an outward port. Of late years several new locals have been started in Trinidad. The trees are planted in squares of from 25 to 33 feet. Experience shows that the greater distance is preferable, and that 40 trees per acre yield as much as 60 trees planted on the same space. To get a revenue from a local takes at least twelve years from the time of planting. Some trees begin to bear at seven years, when the expenses of keeping the land clean diminish : from the twelfth year the net income over expenses increases up to the 25th year, then it remains about stationary for 25 years, when the yield begins to diminish. The average on a plantation or local (of from eight to twenty thousand trees) in full bearing can be stated at eighty nuts per tree per annum.

Cocoanut trees are liable to blight, and also to destruction by lightning. To keep up a plantation young trees have to be supplied continually, but it can safely be calculated that one half of the crop pays for all expenses. In Port of Spain entire coconuts sell at from $18 to $20 per thousand delivered alongside vessels.* In England prices vary from six to ten pounds sterling per thousand. In England entire nuts are preferred, although lately peeled nuts in bags have been shipped there and realized good prices, as they enter immediately in the retail trade. Vessels with asphalt as ballast cargoes carry from 200,000 to 230,000 entire nuts. These are generally sold on arrival to one speculator, who supplies the retail trade with husked nuts and sells the husks to the cocoanut fiber mills. The quantity of cocoanuts shipped from Trinidad from Feb. 1st to Aug. 14th of this year numbered 4,850,118.

CHICORY : A NEW SOURCE OF ALCOHOL.—According to *Erfindungen und Erfahrungen* the celebrated coffee substitute, chicory, seems likely to become of importance as a source of alcohol. The root contains an average of 24 per cent. of substances easily convertible into sugar, and the alcohol obtained by its saccharification, fermentation, and distillation is characterised by a pleasant aromatic taste and great purity.—*Chemist and Druggist.*

* Surely this is an exaggeration : in Ceylon the value is not nearly so much per thousand ready for shipping at Colombo.—ED.

REGARDING INDIAN TEA the *Australian Trade Review* tells us that " as to the quality of this season's crop, examination confirms the reported inferiority in water, the Darjeelings being especially disappointing; while some of the Cachars are also very poor, compared with last season's growth.—*Pioneer.*

COFFEE CURING.—In the early part of last year Mr. D. Morris, director of Government plantations in Jamaica strongly advised coffee growers there to adopt the Ceylon method of preparation in central mills at the port of shipment, but this opinion seems to have been subsequently modified, for more recently we find him deprecating the method employed. He says :—" The pulping and washing does not improve the quality. The sensible Arabs dry their coffee in the pulp, which preserves the aroma of the berry, and is the secret of the value of the Mocha. If dry cherry is sent to the curers here, they at once class it as native coffee, and its value is depreciated. Drying coffee in the pulp will hardly find favour, because the mode of preparation for the market must be altered, and the machinery modified, but the quality will be so greatly improved that the cost of new appliances ought to be of secondary consideration."—*Planters' Gazette.*

A NEW NARCOTIC.—Dr. Schomburgk, the learned director of the South Australian Botanic Gardens at Adelaide, in his annual report on the valuable institution which owes its existence to his unceasing care describes a new narcotic, which the aborigines of Australia indulge in very freely. The leaves of a plant called the *Duboisia Pituri*, which grows in the interior of the island continent, from Cooper's Creek to the Gulf of Carpentaria posses, when dried and chewed or smoked, properties akin to those of opium or tobacco, and probably about half way between these two, so far as potency is concerned. The natives who are fortunate enough—or unfortunate enough as the anti-opium party would say—to find the plant growing wild in their country, trade far and wide with other tribes, who are only too anxious to possess themselves of the means of indulging in the delightful dreamy sensation which the plant produces. The active agent is a volatile alkaloid, similar to nicotine, which has been called "piturine." The "immorality" of the drug will perhaps be somewhat redeemed when we add that this piturine has already been found to be a potent remedy in ophthalmic practice in Europe. —*Colonies and India.*

EUCALYPTUS OIL.—The Mallee scrub is one of the dwarf species of eucalyptus, covering many square miles of the Australian ranges. The volatile oil it contains is an admirable solvent for kowrie and other varnish resins, and it is so abundant that Baron Mueller gave the plant the name *Eucalyptus oleosa.* There is a demand for all the oil that can be produced, and some years ago Mr. Bosisto commenced its manufacture on a large scale at Swan Hill. The cost of transport, and the difficulty of obtaining water brought the enterprize to an end. The railway, which has been laid out to Dimboola, brought the matter up again, and after inspecting the district Mr. Bosisto purchased a homestead on the bank of a river which provides an abundant, supply of excellent water. The Mallee belt, two to five miles wide, runs close to the east boundary of the land for a great distance. Mr. Bosisto has erected the necessary buildings, with pumping engine, four stills 10 feet in diameter, and 8 or 10 feet high, with the necessary worm. The plant will be equal to working off 2 acres of scrub a day. The waste water from the stills will be used to irrigate small paddocks near the works, where attempts will be made to grow various medicinal herbs. On the day of opening, some friends of Mr. Bosisto visited the works, and the success of the enterprize was drunk heartily.—*Chemist and Druggist.*

Correspondence.

To the Editor of the Ceylon Observer.

THE EKMAN PATENT: FIBRES.

London, E.C., 13th Oct. 1882.

DEAR SIR,—The Ekman patent is now getting into work, and Mr. Spicer the great paper manufacturer at Godalming is turning out the paper made in a direct line of machines from the plank of wood.

A friend described to me this morning what he had witnessed in these works. In one part was situated the warehouse into which the export bales are thrown; these have to be cut open and each blade of grass has to be handled by women to ensure all dust, and dirt being removed from it, and he describes it as one of the most distressing occupations he has ever witnessed; the poor women were smothered in dust, and he cannot understand how they can work in such an atmosphere.

The fact is, that any dirt passsing with the grass or fibre into the cylinders destroys the paper in colour and appearance, and this is one of the reasons why wood has such an advantage over grass and reeds, because as soon as the knots are cut out of the plants you have a clean pure substance to work upon. So much so is this the case that Mr. Spicer is actually turning out better paper by the direct process owing to the pulp never having been baled or dirtied *en route* than is being turned out at the Ilford paper works where the pulp is brought from Sweden in cases.

I enclose you a sample of flax that has been simply treated and carded: this costs 10d per lb. to produce including the raw material, and it is sold at about 2/6 to 3/ per lb. It is employed for trimmings and all sorts of purposes where silk was used; in gimps and laces, for furniture, etc., etc. It has an equal appearance to silk when dyed. I need hardly say there are many Eastern fibres that would yield as bright a surface.

I ought to inform you, this sample has not been passed into the last stage of bleaching, but is sufficiently clear for dyeing.—Yours truly.

THOS. CHRISTY.

P. S.—I send you a sample of seeds from a tree that produces the oil of "Ben," the slowest drying oil yet discovered, and is used by watchmakers, and for all delicate instruments. I think it will be largely used when better known.

THE FRUIT CROP IN ENGLAND A FAILURE FOR FOUR YEARS RUNNING.

At Home, 19th October 1882.

DEAR SIR,—The fruit crop in England has this year been a complete failure—far more complete than has ever been known to be the case with coffee. Orchards, from which in average years two or three hundred pounds' worth of fruit has been sold, have this year given scarcely enough to supply the wants of a single household. I learn that this is the fourth yearthat this has been the case; yet people do not there fore take it for granted that England has ceased tobe a fruit-bearing country, nor do they abandon their orchards.

Let coffee planters take heart. If, as is undoubtedly the case here, their short crops have been owing in great measure to abnormal seasons, there may be a good time coming for those who have the courage to wait.

NIL DESPERANDUM.

CEYLON COCOA IN THE EUROPEAN MARKETS; THE MONOPOLY IN WHITE PEPPER.

London, 21st October 1882.

SIR,—In No. 2 of "New Commercial Plants" I gave a description of the cocoa ("theobroma cacao"), and I shewed that the soil entirely ruled the quality of the production. I have sought to trace the destination of the cocoa that is produced in Ceylon, and I think that the result will prove interesting to many.

It is known that the cocoa trees, when young, produce the best cocoa, and that, after their first year or two's fruiting, they are not likely to improve in the quality of the berry either for flavour or for size. It is remarked that the berry of the Ceylon cocoa is small, and to the general observer has not much to recommend it, but nevertheless it commands a high price in the market compared to other descriptions of cocoa. The Ceylon cocoa produces a bright colour; hence it is purchased by the Paris confectioners for the highest class of confectionery, where the colour is shewn and is of importance. It has also rather a peculiar flavour, which is also sought after; hence its high value.

It will be interesting in a few years to notice if these two characteristics can be maintained, because if such is the case, it may make up for a deficiency in the quantity per acre.

The narration of these few facts may cause planters to ship direct to French ports and so save English expenses; or they may incline the planter to further research, to see if all his cocoa yields the same brigot colour and the same bitter in the flavour, because it must not be forgotten that the finest cocoa produced in the world comes from one farm near Guatemala, and that, even at a mile distant, the seed taken from this one farm will not produce anything like the same quality of cocoa.

If planters when sending home crops from new ground, would only ask for a critical report upon their products, they might often do much better than at present, because they now lump their products together, and when the report comes out they cannot tell which part of their estate yielded certain qualities of produce. I am sure this is well worthy of the attention of planters.

Take, for instance, White Pepper. This is produced by skilful native manipulation, and one family of Europeans almost has the monopoly of the very best white pepper. The treatment during the stage of fermentation has been carefully watched for many years, and the quality has been improved from time to time, so that this one house in India commands almost the monopoly.—Yours truly,

THO. CHRISTY.

TRANSPLANTERS.

Madura District, South India, 29th Oct. 1882.

DEAR SIR,—I have found Crosse and Blackwell's empty soup and jam tins very useful of late. Cut the two ends clean out, place over a plant and press into the earth with sticks, take up the plant in tin. The thing is to get it out. Get a roundish bit of wood, say 2 feet in length, cut ends flat or even, take an auger, bore a hole down the centre (say twice the length of a jam tin), burn it out with the pointed end of a spade bar. At right angles, bore another hole at end of the down centre hole, round off a stick for a cleaning rod, stick expeller in the ground, place plant in tin on top—(tap root, if any, passes down centre hole)—and press tin down over expeller and you have plant perfect with a compact ball of earth; its growth unchecked. I was driven to conceive some dodge to get my land planted. It was late in August, and I was planting up to within three weeks of this!—Often, on scorching days, followed by six and seven sunny days. I don't know of a vacancy in the clearing! Two neighbours of mine tried very hard to show me one, but couldn't. A saw, an auger, a pruning knife, a spade bar and a tin cutter may be found on most estates. If ground is hard, water the beds. A bucket of water by the side of the expeller and a heap of ashes will facilitate the operation.

Can you give me any information about paddy-husking machines?—Yours faithfully, PLANTER.

[Paddy-threshing machines were not a success in the Matara district here.—ED.]

THE TOGA MEDICINE.

DEAR SIR,—In your *Tropical Agriculturist* for May the "Toga" *plant* is mentioned, which does not exist, whilst the "Toga" *medicine* is prepared from two Fijian plants neither of which rejoices in the name of "Toga."

Some time ago I met somewhere an extract from the *Lancet* which mentions both plants by their botanical names and correctly, but in which at the same time the second plant seems to be considered as a worthless addition. In Dr. Seemann's work, the one plant is described as Rhaphidophora Vitiensis and the second as Premna Tahitensis (Verbenaceae.) But whilst the Arcidaceous plant gets the credit of being the chief agent, the Verbenaceous plant, the bark of which contains, as most plants of that family do, a decided aromatical principle, which I am quite sure, must not be ignored in the composition of the drug, is denied any share of efficacy.

Of the value of the drug against some forms of neuralgia I have had practical proof in my own family. It was prepared green, fresh from both the plants, every day, and obtained from the bruised stalk of the first and the scraped bark (mezophlebium) of the second by maceration in cold water. It was then pressed in a cloth strainer, and a tumbler full taken three times a day before meals.

The natives often keep it in a dry state in their houses for ready use in balls about the size of a fist. They also employ it externally by moistening and chafing the affected parts. The medicine is called Toga, because it was first used, and the knowledge of it imported into this country by natives of Toga Tabu (Friendly Islands.)—Very faithfully,

JACOB P. STORCK.

CROTON OIL PLANT CULTIVATION.

November 3rd.

DEAR SIR,—In reply to your correspondent "S." of Punduloya, in *Observer* issue of 31st October, wishing me to give a few hints as to elevation, soil, etc., necessary for the success of croton oil plant cultivation, I am glad to be able to inform him that with me it grows in very poor soil and at an elevation from 1,700 to 3,000ft. At the request of a Haputale planter, who applied to me some 2 years back whether I thought the seed would grow on abandoned coffee land and at stake, I replied yes, supplied him with seed and have lately seen his advertisement to sell seed: so he must have been successful and is getting a return the second year. If for a wind belt, plant 8ft. apart, top one plant at 2ft. and let it grow as a dense shrub; the second trim and let it grow to a tree, and so on. You will then get a strong wind belt. If in coffee, cocoa, or cardamom for shade, plant 20 to 30ft apart, trim for trees. Seed can be planted in a nursery and plants planted out same as Arabian coffee (plants or stump,) or seed planted at stake.—Yours truly, J. HOLLOWAY.

AGRICULTURAL PROSPECTS IN THE WEST AND EAST.

Nov. 5th, 1882.

DEAR SIR,—To some there is a morbid satisfaction in learning that they have fellowship in suffering. To the majority of your readers I will not impute this idiosyncrasy: but to shew that we planters are not more in need of pity than our brethren in the old country, I quote from the letter of a large land agent just to hand:—"It is impossible to describe the miserable state agricultural interests have been in for the last four or five years. The glebes have become in this district almost uncultivated; the small squires have to leave their homes and goabroad, and many large estates, where the owner has no money to lay out in improvements, are unlet: for instance ———, ———, ———, &c., and on one estate in ——, which I know there are 12,000 acres of land uncultivated." My correspondent also gives me some particulars of the estates under his own management, and even on these—estates upon which much money is laid out by the owners—there is land unlet. In all of the above cases the land is above the average, situated in the best parts of the midland countries, and land which in my hunting days I regarded as a veritable Goshen.

By the same mail comes a letter from an Ex—planter, who has found a resting-place for the present in Ontario Canada. From the 8th to the 19th of May he, was "stuck fast in an ice floe, entirely disabled, with propeller smashed and drifting more or less with the ice on the coast of St. John's, Newfoundland."—I mean, of course, that the ship in which he was a passenger was in this condition. He isays:—"I hope in time to become a fairly skilled agricultural labourer; for that is about what the ordnary armer is here. * * I guess you would laugh if you saw sometime a refhoeing praties, or mowing, or 'wrastling' with a refractory old 'mutton' Manitoona by-an-bye and mentions "Maintoba mud in the spring 'bud dog' mosquitos in summer (3 of which are said to be able to pull a strong man out of bed) and 30° below zero in winter with an occassional 'blizzard' (t: t: meaning unknowo) will stir up a liver blighted by the withering blast of oriental luxury (save the mark in these days!) and make a new man of you in no time."

To my mind no man who has health and strength and few a hundreds left would do badly to go to the United States (see letter *re* Idaho in the *Field* of Sept. 30th) on Canada; but to many who have lived here for long and become too much accustomed to Indian ways I could not recommend roughing it anywhere. Hard work on a coffee estate is very different work from hard work in these countries, where one has to dispense entirely with the assistance of domestics of all kinds. No friendly coolies, no "boy;" no;—"ruffin" would not suit many of my acquaintance, who *fancy* that they have experienced hard work here. All farm work is very tiring to a novice, and still more unsuitable to a man whose constitution is debilitated by a lengthened residence in a tropical country.—I remain, yours very faithfully. A FARMER OF EXPERIENCE.

P. S.—I think it may be worth mentioning that my letter left Matale on the 22nd August, arrived at Ontario (via a London suburb, where it was re-directed) September 27th; answer Nov. 5th—75 days! Distance: perhaps you will be kind enough to calculate. I enclose the envelope. [About 18,000 miles.—ED.]

ANALOGY BETWEEN COFFEE LEAF-DISEASE AND POTATO FUNGUS.

November 6th 1882.

DEAR SIR,—Having been from home for some time I have been unable to notice "W."s strictures on my letter in which I suggested a possible similarity in the direful operations of *Peronospera infestans* and that of *Hemileia vastatrix*, I am supported in this belief by no less an authority than Mr. Stephen Wilson, with whom I had the privilege, some three months since, of having an interview, in the course of which I learned that his observations and experiments with *P. infestans*, which have extended over some thirty years, had resulted in a very decided

opinion as to the *true* life history, which he held had never been accurately understood or described. The results of his researches into the nature of this fungus as well as that of *Hemileia vastatrix* were imparted to me in confidence, but it will be no breach of faith on my part now to state that they entirely upset all existing theories regarding the former and that he considers Marshall Ward's life history of *H. V.* as incomplete, if not inaccurate. It will be seen in the columns of the "Gardener's Chronicle" of 7th ultimo, that he is now giving the public the benefit of his discoveries, and in subsequent papers he will state his reasons for disagreeing with Marshall Ward, from which a controversy is sure to arise by which the coffee planters must benefit.

It will be unnecessary for me, however, in replying to "W" to rely on Wilson's discoveries.

"W." gives a life history of the deadly fungus (*P. infestans*) which is peculiarly his own or at all events a theory which was discarded when it came to be understood that *Peronospera* was no disease, but only the cause thereof, like *Hemileia* in coffee. His motion that *P. infestans* requires no open door to send its germinating tube through, is not accurate; the belief to this day being (Stephen Wilson expected) that it enters the stoma on the under side of the leaf and I know for a fact that it becomes first visible there. The despatch and ease with which it disposes of its over-hospitable host is readily explained by the nature *of the host*, it being of a succulent consistence of three months' growth, rendering the ramifications of the mycelium, a very simple matter, as compared with that of the *Hemileia*, which is a perennial with its stem, root and branch cells of a hard and close nature, differing therein from its own leaves and rootlets which become an easy prey to the mycelium of *H. V.*

Is it a fact that coffee rootlets have no stomata; some roots have. But even if it were satisfactorily proved that they have not, is it necessary for the fructification of a spore that the germinating tube should enter a stoma! I think not, for did not Marshall Ward by depriving the leaf of its upper epidermis and placing the spore on the leaf cells, prove that germination in this manner was possible? It would not be necessary that a spore germinating on a rootlet should fructify to accomplish the destruction of the rootlet, the mere entrance of the tube would be sufficient in a few hours under certain conditions to effect this. Every planter knows that the roots of his coffee trees are covered with a fungus. May this not be another form of *hemeleia*? In short, with our present limited knowledge of fungoid nature, can any hard and fast line be laid down as to their peculiar proclivities? Plowright has now proved that the rust in wheat is identical with that produced on the barberry leaf, although the spores of the two are somewhat different. A spore taken from a barberry leaf fructifies on a wheat leaf, but the fruit from this will not again germinate on the barberry. The spore of barberry fungus grown on a wheat plant is entirely different from the original. As the editor of the *Gardener's Chronicle* says in reviewing Stephen Wilson's paper on potato fungus [referring to fungi] "the more their history is studied the more complicated does it appear to be. Their construction is simple—of the simplest, in fact; but their habits of life are astonishingly complex." These facts remain, a fungus is present on our roots, a great dearth of rootlets exists which was co-incident with the leaf fungus, what is the connection between them?—Yours faithfully,—J. S.

[We suppose the scientific and the popular explanation of deficiency of rootlets in coffee trees badly affected by leaf fungus has been identical: the debilitating effects of the fungus has prevented the tree from elaborating root lets in normal quantity. And no doubt the same cause, general debility, would render the roots specially liable to attacks of fungi. But this new theory that the root fungi are identical in nature though different in form to that which attacks the leaves, is worthy of full investigation. Surely one of the main positions taken up by Mr. Morris which Mr. Marshall Ward overthrew, was that now apparently adopted by "J. S.," that the mycelium of the fungus covered the stems of the trees?—ED.]

COFFEE CULTURE: A PLEA FOR WEEDS AND FOR LIGHT PRUNING.

DEAR SIR,—When land is kept clean, I do not care what the lay of it is, or how closely drained, there is always a certain amount of wash. Weeds, if returned to the soil, return what they have taken from the soil, and add the ammonia and carbonic acid that they have absorbed from the atmosphere. Again weeds absorb any superabundance of moisture that may be in the soil, and they not only shade the soil but they also shade the roots of the coffee tree and keep them cool and moist and give the tree time to evaporate the sap gently, to elaborate it, so that the breathing pores are not injured or disorganized by a sudden change from cloudy weather to hot, bright sunshine and they so prevent disease. Weeds do not exhaust land;* it is the coffee that exhausts the land. If weeds exhausted land, abandoned land would in time become bare, instead of which each succeeding crop of weeds becomes more and more vigorous, till some jungle shrub creeps in and they multiply, and, if left alone, would no doubt in time revert to forest again. Clean weeding became general since about 1864, from which date coffee commenced to flicker, and how many places have gone out. The proper thing for coffee is a carpet of weeds, and keep it as a carpet, by either pulling up the big weeds and leaving the small ones, or, as they do in some parts of India, cut them with a grass knife, or, if we must do without weeds, we must find something else. Thatch is too dangerous. The coffee tree is a forest tree and all forest trees have their roots shaded and their tops exposed to the sun. There is no limit to the growth of a tree; if there was, after a certain age every tree would be of one uniform thickness. The richer the soil and larger the quantity the more and more vigorous a tree becomes and produces fruit in proportion, but, when there is a falling-off of the essential food, then the tree loses the power of production; a further falling-off, it loses the power of supporting its branches, and if the supply is exhausted altogether, that tree must die; so that, in manuring, the great object is not to manure the tree but to enrich the soil. It does not matter how and where it is placed, if within reach. The same instinct, that makes a creeper find something to creep on, makes a tree know where there is good food to send its roots into. A tree sucks up its food through its small tender fibrous roots and the only use it makes of its larger roots is to prevent its being blown down, (which I do not think there is much fear of in most districts in Ceylon); so that it would be better to cut them back and make them throw out fibrous roots and so give the tree so many more feeders. It was accidentally found in England that, by cutting back the large roots of a fruit tree, it bore better fruit and in larger quantities. No tree ought to have its roots longer than its branches and more especially our coffee. Each tree should be kept to itself, so that any manure put beyond a tree is wasted and misapplied. Forking is sometimes very beneficial. If the soil is stiff and hard, a forking will allow the roots to spread, or, if the roots get too matted, then a good forking will break a lot of the roots, and so open out

*Oh! Oh!—ED.

the roots of the tree; otherwise forking does harm by destroying a lot of the feeders. In former days, if a planter expected a field to bear a good crop, he did not prune it, as most likely he depended on that field for the bulk of his crop. Handling was quite enough for that field: what pruning was done, was done by picked men. Nowadays every man, woman and child that can carry a knife is put on to prune, without regard to climate or condition. In a hot, forcing climate, it is the best thing possible to prune as early as can be done, as the rebound of the sap forced out wood, that wood blossomed and bore crop. In a colder climate, wood takes a year, and sometimes more, before it will blossom, so that any early pruning that is done should be done, not for the coming crop, but with regard to the crop to follow. It is a great mistake, when a piece of fine coffee, in a cool climate, is going to give a heavy crop, to prune it early, to prevent its over-bearing. The rebound of the sap is wood, so that the trees bear wood instead of crop, and most of the manure is cut off and the balance gone to wood. If there is not the means of backing that crop, prune after the blossoming season, and cut off as much crop as necessary, and it should be remembered that the leaves of a tree are the most important part to the tree: they are not only the breathing organs of the tree, but also the stomach. The sap is sent up through the wood to the leaves and is converted by them into proper sap or cambium and sent down by the inner bark, and is the real nourishment of the tree; so that in cutting away a lot of young wood so much of the breathing and digestive powers of the tree have been taken away and the tree must restore these first. If a person gets a fine piece of land, sticks coffee into it, and get good crops, I do not consider that he deserves any credit. Any one can do the same and it is what most of the natives did, till their land became exhausted. A planter ought to know how to assist nature and not leave nature to do everything for him. At one time coffee used to be produced for 40s per cwt, and with means to cultivate properly it can be done again, and now that we know "what ails our coffee", we know how to keep it up,—Yours truly, G. F. HALLILEY.

"WHAT AILS OUR COFFEE:" "ENDOGENOUS" AND "EXOGENOUS" TREES.

DEAR SIR,—In case some of your readers may not be able to understand some of the statements I have made, I write another letter and trust this will suffice. Trees are divided into two sections, endogenous and exogenous. Endogenous, such as palms, sugarcane &c., grow from seed of one lobe, and increase in girth from the inside, their life and growth is limited. we have several examples in Ceylon, such as, the talipot, the kitul and what is most familiar to us all, the plantain: we know that when the heart of the tree comes out in flower and it matures its fruit, its life is ended and though through growing in better soil, some of them may get a great deal larger in stem and height, still they cannot get beyond a certain limit. Exogenous are trees that grow from seed of two lobes and have no limit to their life or growth, as if the world was constituted differently to what it is and was a ball of rich soil, an exogenous tree would go on growing till the roots came out on the other side and would only die because they had no more soil to grow in and can any one limit the growth of that tree? It has been suggested that diseases are contagious: the thing is preposterous, if such a thing were possible there would not only be no tree on the earth, but no green thing; insects may spread, but such a thing as disease is impossible; the influence of weather on impoverished sap is the only cause of supposed contagious disease. Thus, for instance, when a piece of cinchona dies out, why does it leave patches? Merely because those patches have the required amount of *the* food of *the* tree, and it has been found that land where cinchona has died on will not grow cinchona again. Why? Because it has not the necessary food for cinchona, and, to replace the elements to allow the cinchona to grow, we would have to find out some manure that would produce quinine, if such a thing could be found. I have no doubt that the chemist would extract it cheaper than we could, by growing cinchona. Imperfect flowers have been mentioned. In a *really healthy coffee* tree, such things are almost impossible; imperfect flowers are abortions and such can only be produced by weakness, disease or both combined, such a thing might also happen after the berries have formed, to a weak sickly or diseased tree, by some shock to the system from causes explained in my other letters, but to a really healthy tree it could not occur. Coffee (unlike cinchona and gums) has been supplied by nature with a provision (but for which Dr. Thwaites' prediction would have come true), and that is as soon as the sap is disorganized, the tree either shakes its leaves off or the leaves drop off of their own accord, but it is a certainty, that if these leaves instead of dropping off, had sent the sap down by the inner bark, there would not be now enough coffee trees to supply the Y. A.'s with walking sticks. Now what do you and your readers think of coffee and of "what ails our coffee?"—Yours truly,

G. F. HALLILEY.

VINE CULTURE IN CEYLON.

Colombo, Nov. 9th, 1882.

DEAR SIR,—I observe that you in a footnote to my letter of yesterday suggest, that the wine sent to Spilbergen and his companions by the King of Kandy was the produce of the coconut. This is totally inconsistent with the original. The word "*druif*" translated by me as vine is strictly speaking "grape" whereas the equivalent for coconut in Dutch is "*klappus.*"

That the vine attains a considerable size in Kandy, even at the present date, may be proved to the satisfaction of any one interested. At the back of the Kandy jail is a very fine specimen. It used to yield large crops in the time of Mr. Braybrooke, but has not done so since the jailer, in his anxiety to increase the supply, buried a cart-load of dogs (obtained through the police in the dog-killing days) at its roots. The manure was evidently too stimulating though probably a pariah or two might have proved highly beneficial.

The secret in vine culture in Ceylon seems to consist in knowing what is the best season in each locality to submit the plants to an artificial wintering by laying bare the roots, and also the correct period over which such wintering should extend. Surely some correspondent in the Northern Province could give us, through your columns, the required information as far as Jaffna is concerned.—Yours faithfully, BLANK.

WEEDS ENRICHING AND SHADING THE SOIL

Dumbara, 14th November 1882.

DEAR SIR,—The editorial "Oh! Oh!" to the contrary notwithstanding, it appears to me that Mr. Halliley is justified in his statement that weeds enrich the soil (if not removed from it, always understood), while coffee exhausts it; as weeds, allowed to grow, mature, and die down on the same spot, must return to the soil with interest whatever they have taken from it, whereas the most soil-exhausting part of the coffee plant, the seed, is systematically removed. Be-

sides their obvious usefulness in checking wash, weeds must improve the mechanical condition of the soil by decaying in it as they are forked in from time to time, and, in order that they should act beneficially, it is absolutely necessary that this should be done occasionally. That they keep the soil moist and shaded is, I think, proved by the following, which is the first result I have to chronicle from an experiment already commenced on this estate and carefully watched, of whose progress I will send you occasional notes. The late spell of dry weather which killed a lot of young cocoa plants, though shaded, and caused the coffee to droop in a field which was kept clean and where the soil is deep, had no injurious effect upon similar cocoa (but not shaded artificially) and coffee growing through a carpet of weeds in an extremely rocky (limestone) field.—Yours truly, G. B.

THE FIVE-BEANED COFFEE BERRIES, sent to us by Mr. J. L. Dewar, were submitted to Mr. A. Dixon of the Royal College, who reports:—"They are perfectly *normal* as far as the natural build of the flower is concerned. Each alternating whorl in the flower consists of the same number of parts, thus: calyx teeth 5; corolla lobes 5; stamens 5; beans 5; we cannot give diagram). From some disturbing cause of nature suppression of 3 ovules is the rule* (although 4 are often suppressed as in peaberry coffee.) We have instances of the same in the coconut. Occasionally, we find one strictly normal, but the rule is suppression of 2 ovules. In the English oak *one* ovule usually destroys the other five and the 3 septa."

FORESTRY.—Major Van Someren's report on Forest, Administration in the Pubjab gives an interesting account of the experiments made by the department during the year. The Carob trees at Changa Manga flowered for the first time last December, and are reported to be looking healthy; as also do the Carobs at Lahore, where there are 500 young plants in pots, and 80 planted out. Twenty-two kinds of Eucalyptus were sown in the autumn of 1881, and, by the following spring, 4,000 seedlings were in the beds. At Sabathu, Eucalypti have been a failure. From Changa Manga it is reported that *Eucalyptus Rostrata* thrives better than any other species, and is less liked by white ants. Thirty new Spanish chesnuts were planted out at Kilba on the Sutlej. Some of the older trees fruited, but the *burrs* were empty. The seed tried at Chumba all failed from being too old and rotten. Cork oaks and French olives are both doing well in Kulu; and something that is called *Catalpa Bignonioides* flourishes both in Changa Manga and Kulu. In Kulu, also, the Tasmanian blue gum (*Cupressus Macrocarpa*) is thriving.

THE INDIAN SILK TRADE is likely to have a prosperous season, states the Lahore paper. The weather has been singularly favourable, and cocoons are reported to be more than usually. The silk cultivators in India, have to contend against peculiar difficulties. Labourers are ignorant and careless. The *gomashta*, in nine cases out of ten, oppresses the spinners and robs his employer. The silk-worm is of inferior quality, and the improvement of the cocoons is interfered with by the general rack-renting of mulberry lands. To add to these troubles, M. Pasteur has at last discovered the cause of the disease which has afflicted the silk-worm in Europe for the last twenty years; and at the same time it seems that the increased ravages of *phylloxera* in France and Italy is likely to divert much capital from the wine to the silk industry. Still, the Indian grower need not despair as long as he has his six harvests of cocoons in the year, to the single European harvest.

PLANTING IN THE WYNAAD.—October 18th. We are very thoroughly enjoying ourselves. Every living thing, except the weeds, is revelling in the mere fact of being alive, for our almost forgotten friend, the sun, is graciously pleased to shine on us once again. Crop is bound to be a tedious business this year; more than half the berries are only partially formed, and fears are felt that much will prove light—mere floaters in fact—when pulping commences. I have never seen the trees themselves looking more luxuriantly healthy. Little or no signs of leaf-disease, that is a joy, in anticipation, sure to come to us with the weather. Cinchona is splendid. The growth during the past year has been extraordinary, in spite of the damage done during the heavy bursts of the N. W. Monsoon. Coffee is to be regarded as a mere "pot boiler" apparently, whilst, following modestly in the wake of the great King Ledger, we hear of pepper, rubber, ipecacuanaha and tobacco; all of which, it is believed, would flourish satisfactorily in our climate. Tea, we know, has been successfully tested in this respect; and the demands for the comparatively small quantity already produced in Wynaad should be sufficient encouragement to induce others to attempt its cultivation thoroughly. Anything that will thrive on plenty of wet weather ought to do in Wynaad; products with a *rooted* objection to 300 or 400 inches of rain in the year are better elsewhere.—*M. Mail.*

LIME.—Referring to our remarks in a recent issue, on the presence of lime in the irrigation canal water of Dehra Doon, and on the unsuitability of lime as an ingredient in the soil for tea cultivation, we have come across the prospectus of a certain patent manure-maker, who takes care to point out that the article he manufactures, has no lime whatever in its composition. No doubt experts in this speciality are thoroughly up in their subject, and have found that a manure containing lime, such as might be suitable for coffee cultivation is deleterious for tea. The following analyses of soil from Assam, the home *par excellence*, of the tea plant, were made by Dr. Voelcker, well known for his labours in connection with agricultural chemistry:—

	VIRGIN SOIL.	OLD SOIL
Water ...	4·54	5·33
Organic matter ...	4·94	4·75
Nitrogen ...	·44	·13
Silica ...	76.14	74 66
Soda ...	·28	·17
Potash ...	·25	·27
Magnesia ...	·18	·26
Lime ...	·09	·14
Oxide iron and manganese...	8·21	7·41
Alumina ...	4 15	5·94
Phosphoric Acid ...	·13	·16
Sulphuric acid ...	·16	·13
Chloride ...	*trace*	*trace*
Carbonic acid ...	·06	·21
	99·43	99·43

On the other hand an eminent firm of coffee-manure manufacturers, advertize their speciality ascontaining:—

Phosphate of lime	22·93
Sulphate of lime	22.15
Total ...	45·08 per cent.

It will thus be seen that the utmost care should be exercised in selecting manure for tea purposes, and that it will not do to use any sort of manure or fertilizer, on the plea that good manure cannot fail to strengthen the plant.—*Indigo Planters' Gazette.*

[If lime is so objectionable in manures for tea, there will be great difficulty in dealing with tea and coffee planted together. But we suspect that a moderate quantity of lime is needed by tea as by most other plants.—ED.]

THE TEA SEASON in Assam is about to close (says a proprietary planter writing on the 10th ult.) with a very large increase on the outturn of last year, but owing to the state of the market it is very doubtful if last year's profits will be reached by many estates.

TEA.—The Lieutenant-Governor of Bengal has come to the conclusion that it is his duty to maintain the restrictions already imposed on the extension of the tea industry in the Darjeeling hills. Mr. Rivers Thompson has received several applications from capitalists for grants of waste land in the Darjeeling district; but several of these he was obliged to refuse. In the first place, in the interests of the Indian public, the cinchona reserves must not be encroached upon. Secondly, the hill sides are being denuded of trees already, to a dangerous extent; and lastly, the native population is rapidly increasing; and land must be reserved for native cultivation.—*Civil and Military Gazette.* [One effect of this policy will be very largely to enhance the value of lands held by private parties.—ED.]

CROPS AMD FUNOI: CAUSES OF PESTS AND REMEDIES.—Our readers will be interested in the following paragraph, which we quote from Mr. Robertson's report for 1882 on the Saidapett Farm, Madras :—"The early-sown crops were generally free from 'fungoid' diseases, but the later crops were, in several instances, severely attacked by 'rust,' the result chiefly of the bad climatical conditions, which characterized the latter portion of the cold weather cropping season. Neither 'smut' nor 'ergot' were observed on the crops. This, probably, was due to the fact that the seeds were, in almost every instance, dressed with sulphate of copper, before being sown. The process followed, is shown in the following directions :—'For 50 lb. of seed, take 3 ounces of sulphate of copper, which dissolve in one quart of hot water; when the solution is quite cold, pour it over the seed, and mix thoroughly; when quite dry, the seed is fit for sowing.' The object in dressing the seed in this way, is to kill the fungoid spores that may be mingled with the seed; this dressing, however, does not appear to have any marked effect in preventing attacks by 'rust.' Of course, if straw is used, in bedding the cattle, which has been attacked by fungoid disease, and the manure of which this bedding forms a part, is applied to land, the probability is that the spores of the fungus will be conveyed to the soil at the same time, and in this way the spores may get into the plants, even though the seed, from which they were raised, was chemically prepared. There is, however, one clear advantage in thus dressing the seed, irrespective of any effect that may be produced in checking fungoid disease; this is, in preventing the coolies from eating the grain when they are sowing it. In other countries the loss, in this way, is too trivial for attention, but in this country, where four or five men are usually employed to do work for which in other countries one man would be employed, and where, the people are grain-feeders, and frequently only half-fed, the consumption of grain during the sowing process is often a most serious evil; not so much on account of the value of the grain as, because the land is frequently only half-seeded—a fact which is disclosed only, when it is *too late* to remedy the evil. The paddy crops of the farm were attacked by a fungoid disease, and afterwards by insects. The cause was the mismanagement of the irrigation water, it having been allowed to stagnate, by too long retention on the land. By draining off the water, and drying the land for a few days, the crops recovered completely from both attacks." There is here a hint for the improvement of paddy cultivation in Ceylon, which Government Agents and their Assistants ought to impress on the goyas.

YATIYANTOTA (Ceylon) has, for some time back, steadily risen in favour as a tea district, and now that Mr. W. H. Morrison of Mepitiakande, has topped this season's prices for Ceylon tea with 2s 8½d for his broken pekoe, we may be sure that further attention will be directed to the neighbourhood. Mr. Morrison has already been instructed to begin opening the 500 acres of forestland purchased by Mr. J. H. Young of Dambulagalla and Petikande. It may be mentioned that on Mepitiakande as yet, no machinery has been introduced in the preparation of the tea, although in respect of rolling especially the saving of labour from the use of machinery is very great.

TEA GROWN NEAR GALLE.—Mr. Ziegan has sent us a packet of excellant Pekoe tea grown and prepared on his estate near Galle, and writes as follows:—"I have to thank you for the paragraph you inserted in the *Observer*, referring to the sample of tea I left with you some short time ago, and am pleased to hear your favourable opinion of it. I scarcely, however, expected so favourable an outturn, it being the first manufacture on the estate and which will account for any faults the tea may still possess, such as a badly rolled leaf, the greyish tint in the 'Pekoe Souchong', and perhaps a slightly pungent taste, owing to the freshness of the tea. These faults I hope to remedy in time. Still it goes to show how suitable the lowcountry in this island is for the tea plant, even if grown in the very valley as this has done and with every appearance of it turning out a profitable venture. For your information, I may remark that the tea in question is grown from some of the best seeds imported from Assam, that the place it grows on is called 'Citrus' estate, lying at a distance of 8 miles from Galle, and that it thrives well from the very road side to a height of about 180 feet. I send you a small packet of the 'Pekoe' which being now a few months old, will, I trust, be, still more palatable than the comparatively new sample."

THE QUANTITY OF CINCHONA BARK now exported annually from India is becoming large, and it is encouraging that certain vaticinations regarding value have not been verified. It was thought by many that an increased supply would so reduce the price, that the bark would not be worth cultivating. This has not been the case, and for this reason; quinine is an article of general utility, and the demand is therefore expansive. The Madras Government has issued a return showing the results of the last six years in the cinchona industry on the Nilgiris. The following tables give the details of the plants in existence, and the annual outturn :—

		Number of plants in the Gardens.	Produce, in lb.
1876-77	...	42,208	103,341
1877-78	...	204,434	138,808
1878-79	...	818,885	114,320
1879-80	...	1,525,285	179.299
1880-81	...	2,612,922	243.245
1881-82	...	2,963,287	242,052

The cost of producing and the returns per pound are, so far as available, given in the next table :—

		Cost per lb.	Price per lb.
1876-77	...	R0 9 3	R1 10 8
1877-78	...	0 8 0	3 13 5
1878-79	...	0 10 4	2 9 5
1879-80	...	0 8 7	3 0 0
1880-81	...	0 6 3	2 8 0
1881-82	...	0 7 5	?

The average profit was therefore about R2 3 2 per lb. The acreage is given at 847 during the last year under notice, so that the year's profit (1880-81), of R336,095, was equal to R396 per acre, a result which ought to make a tea-planter's teeth water.—*Friend of India and Statesman.*

THE EKMAN FIBRE PATENT continues attract much attention in England. We hear that Mr. Routledge, the great authority on the treatment of bamboo, having given Mr. Ekman some of the thin bamboos, was greatly pleased with the pulp made from them by the new process. He went next to the works with large bamboos, watching them being liquified into pulp. It is expected that in all probability he will adopt the Ekman process. Mr. Routledge has done so much for the advancement of the fibre trade, not always with success to himself, that his interest goes far to prove the value of the Ekman process when so good an authority takes it up.

PLUMBAGO.—A piece of black lead appears to have been named on much the same principle as that followed in naming the Speaker of the House of Commons. The Speaker is a man who does not speak; the black lead is a substance which contains no lead. It is true that a piece of black lead presents characters which, at first sight, are strongly suggestive of a metal; but it is easily shown that these characters are only superficial and delusive. If we split open a lead pencil, and extract the thin rod which forms the axis of the cedar cylinder, we obtain a body which resembles a metal, inasmuch as it processee a dark iron-gray or lead color, coupled with exactly that kind of luster which we generally regard as characteristic of metallic bodies. The surface of a compact piece of metal always presents a peculiar brilliancy, due to the fact that much of the light which falls upon the surface is thrown back instead of passing into or through the substance; in other words, the light incident upon the surface is neither absorbed nor transmitted to any considerable extent, but is almost wholly reflected or scattered. Now, there are but very few substances, except metals, which possess such a condition of surface as to produce this metallic sheen. Iodine is one of these non-metallic bodies that look like a metal, and black lead is another. It is mainly in consequence of the metal-like luster a black lead that the material is so largely employed as a polishing agent. When the housemaid rubs the powdered substance upon the cast-iron grate or fender, she produces a reflecting surface which has a metallic appearance; and, at the same time, the thin coating which is thus applied serves to protect the underlying metal from rust. In like manner, though for a different reason, black lead is extensively used for polishing certain kinds of gunpowder, especially the coarse-grained powder employed for blasting in mining operations. The powder is placed, with the finely-divided black lead, in revolving barrels, and the grains receive a glaze or varnish which protects them from absorption of moisture. Any conclusion as the metallic nature of black lead which may have been suggested by the lustre and color of the mineral, is likely to be rudely shaken on noting its specific gravity. By merely poising a piece of black lead in the hand, we may observe how light it is, compared with ordinary metallic bodies. In fact, the specific gravity of black lead is but little above 2—that is to say, the mineral does not weigh much more than twice its own bulk of water. Advantage is sometimes taken of this comparative lightness in dressing black lead for the market. It frequently happens that a rock may contain scales of plumbago disseminated throughout its substance, so as to form what has been called "black lead ore." In such a case it is possible to separate the two substances by crushing or stamping the ore, and allowing the fine fragments mixed with water to flow over a mechanical contrivance, in which the light scales of black lead and the heavier stony particles roughly sort themselves by virtue of this difference of density. It is scarcely conceivable that these light scales of plumbago can contain a metal so heavy as lead.—*Manufacturer and Builder.*

THE MADRAS CINCHONA GARDENS.—The *Gardeners' Chronicle* reports that Professor Lawson is about to vacate the Professorship of Botany at Oxford, to assume the post of Superintendent of the Government Cinchona plantations, Madras. Professor Lawson will carry on analyses of bark; no doubt in connection with experiments in culture. His annual reports will be looked for with much interest.

VINE CULTURE.—The vine no doubt grows in Colombo, but it does not pay the trouble and time spent upon it. A good vine is a rarity in Colombo: its favorite home in Ceylon is Jaffna, whence large supplies of grapes are regularly received in Colombo. There it flourishes and yields large returns. It is found almost in all houses in the town of Jaffna, but it is to be regretted that its cultivation is not much attended to, and some old trees which had existed from the time of the Dutch* have lately disappeared and no attempt has been made to find successors to them. The manure used is, cow dung, dried and simple. It is applied immediately after pruning. At no time was vine cultivation on a large scale carried on in Jaffna, and why it has not been done is surprizing.—*Cor.*

REFINED COTTONSEED OIL AS A SUBSTITUTE FOR LARD.—At the last regular meeting of the Baltimore Grocers' Exchange the committee on cottonseed oil as a substitute for lard, composed of Messrs. T. A. Agnew, A. N. Crowder, and W. A. Oliver, submitted their report as follows:—Your committee deem it not out of place, in speaking of cottonseed oil, to give some account of the method of saving or picking the crop of which it is so important a factor. The cotton, with the seed imbeded in its midst, and adhering to it, is picked from the bolls with the fingers, placed in baskets and carried thence to the gin-house. Here, the lint or staple is separated from the seed, and the latter are transported to the oil mills, where they always command the cash. The greatest care is taken to prevent them from getting wet after being ginned as they easily ferment and spoil in this condition. Connected with the machinery of the mill is a delicate and costly attachment known as the "Decorticator," into which being first thrown, the seeds are, by a subtle process, relieved of the hull or outer covering; thus stripped, the kernels pass on into the jaws of the crusher, a machine of tremendous power, where the oil is expressed. In its crude form it then goes to the refinery, where, by repeated processes of heating, the refuse is thrown off, and the product assumes the limpid light yellow appearance so familiar to good judges. There is absolutely no foreign substance used in any of the places of manufacture, so at least your committee has been informed and believes, and the "refined article" is the native product of cottonseed, pure and simple, with its ordinary impurities removed. The very important question now arises, whether this oil is really what it claims to be, a healthful and nutrious article of diet, and whether it can supply the place of lard. Your committee have used due dilligence in arriving at facts, and beg leave to report that all evidence goes to confirm the previous good reports. From the most reliable sources comes testimony that cannot be questioned. In the South, citizens of high standing, among whom are business men, physicians and scientists, unite in declaring that the use of cottonseed oil for the table is conductive to health, and that it can supply the place of lard perfectly. Here in Baltimore, where for five months the test has been applied patiently and thoroughly, your committee have at their disposal the names of many well known citizens who have became converts to the "new departure."—*Oil and Paint Review*

* Can our correspondent prove that Jaffna vines have been cultivated for over 80 years? We do not doubt the fact, but would like to know if there is any local authority on the subject. Cordiner mentions the grapes of the north.—ED.

PLANTS FROM THE NORTHERN TERRITORY.—The Minister of Education has received from the Northern Territory some very good samples of the produce of one of the plantations there. They comprize maize of both kinds, cotton, tobacco, and coconuts. All save the coconuts, which were evidently plucked too early, are so excellent as to leave no room for adverse criticism by the greatest critic. They were produced without the use of any scientific aids to cultivation, and the tobacco was simply dried in the sun. They come from Messrs. Harris and Head's plantation, near Delissaville, on Cox's or Douglas's Peninsula, about eight miles from Palmerston, across the harbour.—*South Australian Register.*

A HILL MODEL FARM: AN EXAMPLE TO FOLLOW AT NUWARA ELIYA.—The *Asian* learns that "a model farm has been started in Bengal as a private speculation. We allude to Dr. Greenhill's farm in the Darjeeling district, which he is just now beginning to get into working order, and which he intends to spare no expense in working in a proper manner. As a proof of this we may mention that he has just brought out from England a practical gardener and herdsman, the former to look after the land and its products, and the latter to look after his herds and flocks. The extent of the holding is, we understand, about 5,000 acres but part of this will be devoted to tea, part of course consists of woods and jungle, with some land not suited for anything but grazing. It is as a stock farm for the improvement of the breeds of cattle, sheep and pigs that a great part of the efforts will be devoted to though the Doctor intends also to become a market gardener, and to grow vegetables and fruit for the supply of the Calcutta and Darjeeling markets. This, however, is at present in the womb of time. What has been actually carried into practice is the establishment of a small part of the stock farm. We lately inspected at Messrs. Cook & Co.'s stables, of which firm Dr. Greenhill has been the senior partner for many years, some of the animals with which it is proposed to encourage the natives to pay more attention to their live stock. As the native mind is fully capable of appreciating any improvement that is likely to result in an increase of rupees in his own pocket, we think that the experiment ought to be a success. First we saw some well-bred and well-shaped pony stallions, which if crossed with the Bhootea ponies would certainly improve the breed. Then there were three yearling bulls—a Devon, a shorthorn and a half-bred Ayrshire, all well grown and handsome specimens of their class, and not too heavy for the country cows. Then came five cows—two Ayrshires, one a magnificent animal, of great length along the back, with great girth, and short well-shaped legs, two shorthorns and a Hereford. As some of these give twelve quarts of milk daily, Rambux ought soon to see the advantage they possess over the country cow, advertised, as when in full milk, to give five seers daily. Besides, the increased size it makes them all the more valuable for the butcher when that destiny awaits them. In addition some Guernsey cattle, rams and ewes, and boars and sows of the best breeds, will be imported, and we believe that even geese, ducks and poultry will not be forgotten. Dr. Greenhill has kindly invited us to go up and inspect his arrangements—an invitation of which we hope to be able to take advantage, as then we may be able to give a better description of what is being done. But now all we can do is to wish him every success, convinced that if he succeeds he will have proved a real benefactor to the country." We are aware that a proposal was made to the Ceylon Government to establish a farm after this fashion without costing the revenue a cent; but so far it has not been responded to.

THIS YEAR'S JAVA COFFEE CROP is officially estimated at 1,030,800 piculs in the latest returns.—Straits *Times.*

THE SOIL OF INDIA AND NITROGEN.—The following extract from a notice in the *Pioneer* of the report on the operations at the Cawnpore Experimental Farm during the rubbi season, 1881-82, is interesting in connection with recent discussions:—"The experiments in manures were supplemented by a careful analysis of the soil of one of the unmanured plots made by Mr. S. A. Hill of the Muir College. The chemical analysis, and the results of the experiments with different manures, go to prove that the chief requisite for fertility wanting in Indian soil is *nitrogen*. This is a most important discovery, as henceforth one main problem of practical agriculture in India will be to supply nitrogen in the form of a cheap manure. Irrigation experiments showed that a single watering more than trebled the produce. There was no rain worth speaking of during the whole of the half-year, yet the natural moisture in the soil was sufficient to germinate the seed sown in the middle of October; and Mr. Fuller adds:—'When there are facilities for cheap irrigation, such as are enjoyed by the farm, the occurrence of winter rains is not a matter of importance. Indeed, it is probable that the total absence of fungoid disease (rust, smut, &c.), which characterizes a dry, cold weather more than compensates for the expense of having to give (say) three waterings, instead of one or two.' Well-water proved more efficacious than canal-water—a result which Mr. Fuller considers surprizing, and refuses to accept as conclusive." If the well water was permeated by salts, as the Jaffna wells are, we see no cause for surprize.

THE WEATHER AND CROPS IN DEMERARA seem to be all that could be desired, and it is refreshing to hear of the prosperity enjoyed by the colonists. We quote from the *Royal Gazette*:—"The weather they have experienced has been as hot and 'steamy' as is usual at this time of the year. But, while unfavourable for out-door sports, it has been almost unusually suitable for the development of the cane-pieces. These are now becoming rapidly in a condition for reaping, and the weight of cane in them is quite unprecedented. The 'arrow' is coming out fast and will soon commence to fade. The chimnies of each estate in the colony will soon be belching forth their clouds of smoke, and will continue to do so until the end of the year. Estates will have hard and uninterrmitting work to 'take off' all the canes due for this season. We trust they will experience favourable weather for their reaping operations. The shipments of sugar to date amount to close upon 85,000 hhd., and are nearly 30,000 in excess of the same period last year. The health of the colony is, on the whole, extremely satisfactory, the principal complaints at present being 'sun' colds and low fevers.' But there is a very dark side to the picture:—"The Registrar-General's return for last year, lately published, and which has already been commented on in these columns, and by our contemporaries, has drawn attention to the enormous death-rate of the colony, when compared with its birth rate. Dysentery and diarrhœa, phthisis, fevers, convulsions, debility and marasmus, dropsy and thrush, are shewn to be the chief causes of this deplorable condition of the public health, and claim for their victims *five thousand and twenty-two* out of the eight thousand and ninety-five deaths recorded. As these are all, to a considerable extent, at least, preventative diseases, the 'Report' furnishes grave and important subjects for consideration."

AN AGRI-HORTICULTURAL EXHIBITION IN COLOMBO is likely to be arranged for the month of May next under Governor Longden's patronage. A Committee has been appointed in Madras to arrange for an Agricultural Exhibition to come off there in February 1883. For this Exhibition, which will be confined to Agriculture, a Government grant of R16,000 has been made, and it is intended to call the attention of Australian and American as well as English authorities to it.

THE CAUSES OF LOW PRICES FOR TEA, are thus noticed by the *Indian Tea Gazette*:— * * *

And first comes in China, which must ever be the great disturbing element. It is a fact that China teas have latterly improved considerably,—or rather as it should more correctly be put, China has sent better teas forward to the London market. At the same time, unfortunately, the quality of our teas this season has not been generally of a high standard. Home buyers, therefore, have shown a tendency to veer round to their old love—China, from whose teas, as being cheaper, they can make the most money. They believed in and required Indian teas so long as they were over and above all others in strength and quality, because these were needed for admixture with poor and cheap China grades; but when the latter are supplanted by improved qualities, dealers begin to think they can, to a larger extent than formerly, do without Indians. That is one cause of the decline, this season, of prices. But there is another reason, and that is the quantity produced. It by no means follows, however, as it has been affirmed, that this is due to over-plucking. Natural causes at work lead to an inevitable increase of quantity, and this has tended to bear down the market. We have not availed ourselves to the extent that we should have done, of the Australian and American markets, and the ridiculous spectacle has been lately seen of Indian teas shipped to London being re-shipped from there, at a considerable profit, to Australia. But all this profit has gone into the pockets of Mincing Lane buyers, and not into those of Indian owners. But there is a third and more potent reason for the prevailing depression in prices, viz., in the quality of this season's growth. This defect has been almost general, and therefore can partly be ascribed to climatic conditions. Planters have not become less skilled than they were, or less mindful of the necessity for making good tea; but if, as has been the case lately, larger quantities of leaf come in than have been reckoned upon, and you cannot fire off fast enough, the inevitable result will be inferior tea. It is not every tea factory that possesses the requisite provision for an unexpected yield, and in fact most factories are provided only for a minimum out-turn. The argument is, therefore, that the *manufacturing* capabilities and facilities of every estate which desires to do well should be kept at the highest point. Extensions go on, plants come into maturity, yield inevitably increases, but the Tea-house accommodation more often than not remains the same, and proprietors only spend money in enlarging their buildings and plant when they find they cannot possibly help it. The fact should be recognized in advance, that all the appliances for manufacture should precede the increase of yield, and be arranged for in time to meet that increased yield when it comes. What we have to do, it seems to us, is to keep up our standard of *quality* to the highest figure. To do this, every effort should be made to provide adequate factory accommodation and appliances. We do not believe that either agents or brokers have recommended coarse plucking this season, but a certain amount of leaf is necessary to make a garden pay. It won't do to make, as a Director once suggested, "all pekoe." We must steer between the two extremes. We must get a fair amount of leaf, and must manufacture that up to the highest point of excellence, and those owners will do wisely who provide their managers with factories suited to the growing capacities of their gardens.

THE "TROPICAL AGRICULTURIST."—*A Monthly Record of Information for Planters. (Colombo, Ceylon: A. M. & J. Ferguson.)*—The planters of India and Ceylon have an able paper in the *Agriculturist*. It is deserving of commendation from our point of view for the closeness with which it adheres to its own special sphere, and for the careful and exhaustive manner in which subjects connected with the planters' occupation are arranged and dealt with. The information contained in reference to the cultivation of coffee, cocoa, sugar, palms, rice, &c., is of special interest to the English reader, but with respect to the rise of the trade in cinchona our interest is considerably heightened by the present admitted position of this bark in the British pharmacopœia and the boon which it confers from its medicinal qualities, not only in the treatment of human ailments, but those of animals also. For in dealing with diseases of cattle, sheep, horses, and dogs, cinchona bark alkaloids are just as valuable as in the case of human patients. It has been the best friend that the emigrant, the traveller, or the soldier ever had. In the swampy and malarious regions of the earth, as well as in the hot alluvials, and deltas of the tropics, it is an agent of relief to the suffering. We are not surprised, therefore, to learn from the periodical before us that the commerce in cinchona is flourishing in India, Ceylon, and Java. The exports to this country in 1877 amounted only to 3,912,000 lb., valued at £402,000. In four years' time, however, that is in 1881, the exports had increased to 14,024,000 lb., valued at £1,812,000. Meanwhile the price had risen from 2s. per lb. to 2s. 7d. In conclusion, we may say that the *Tropical Agriculturist* contains an abundance of facts, discussions, and statistics of quite as much importance to the botanist as to the agriculturist.—*Land*, London, October 7th.

HYBRIDIZATION OF PLANTS.—The *Gardener's Chronicle* says that, whatever general rules anatomists and physiologists may lay down, the practical cultivator has to take into account individual peculiarities. A hundred and one varieties may own one common parentage, but very many of these are as distinct as, and even more so than, many reputed good species. Our contemporary continues:—"This was a vexatious anomaly, not to be explained in pre-Darwinian days. It seems simple enough now in these days, when the significance of variation is appreciated, and the process of evolution can often be seen in action. But it certainly does require us to attach to the word "species" a very elastic, a very arbitrary—shall we say Pickwickian sense?—or rather we are constrained to use the term as one of convenience only, and to admit that what we choose to call species and those groups which exist in Nature—that is, if they really do exist—are often widely different. The test of a species is more difficult to find than ever. If we adopt community of origin we have often no proof of the alleged fact, and we have no means of knowing how far back we have to go to find the common parent or of tracing all the descendants and their intermarriages. If we take fertility as the test, that proves a fallible guide too, for every hybridizer knows that cross or hybrid fertilization between some species is much more certain than self fertilization or the union of plants of the same species." Grafting also affords no better test, as is instanced by the yellow currant forming a good stock for the gooseberry, while the red currant refuses to bear its near ally. As instances of the effect of individual peculiarities within the limits of the same species, the potato and roses are quoted, the varieties being so great, and the effects of disease on those varieties being so different. Our contemporary concludes as follows:—"The relative hardihood of plants derived from the same source is also markedly different. Such instances are so familiar as to need no illustration; but they one and all point to the necessity for keen and persistent processes of selection on the part of the gardener."

PREPARING PEACH STONES.

Several have asked how to prepare peach stones for planting. They are probably aware, that when the stones are kept dry all winter and then planted in spring, very few, if any, will germinate. In nurseries, the stones are not allowed to get very dry, but they are stratified or bedded just before winter sets in. The usual manner is to mark out the limits of the bed and spread the stones over it to the depth of two or three inches; the stones are then spaded in as if turning under a dressing of manure. By this operation they are distributed through and well mixed with the soil, where they are left to freeze and thaw all winter. This treatment causes the halves of the stone to separate and the pressure within of the swelling seed can push them apart. This may be effected by other methods than that of spading in. The stones are sometimes spread upon the ground and covered with spent tan-bark or sawdust to the depth of three to five inches, and thus exposed to the weather. In spring, when the ground is ready to plant, the stones that have been spaded in are separated by throwing the soil of the bed upon a riddle, such as is used by masons; the earth falls through while the stones are left upon the riddle. Those that have been under tan or sawdust are more easily recovered at planting time. It is to be assumed that those who at this time ask what is to be done "to prepare peach stones for planting," have as yet done nothing with them, and that they are still dry. Such should at once be mixed with sand, or sandy earth, in a box, and placed where they will be exposed to all the changes of the weather. This will place them in a condition similar to those that have been spaded in, but having been dried for some months, it is likely that a share of them will remain unaltered, and that in spring the halves will remain firmly together. Such stones must be carefully cracked, holding them between the thumb and finger upon a block and striking the edge with a hammer; the kernels being thus removed, are to be mixed with earth or damp moss, and kept in a warm place until they germinate. The stones that have been bedded or otherwise exposed to the action of frost, and are still unchanged, are not planted with the others, but are separated from those that have begun to germinate, and cracked before they are planted.—*American Agriculturist.*

SUGAR PLANTING IN QUEENSLAND.

The *Wide Bay News* gives us rather a startling item of intelligence. It says that the last new idea (among planters we presume) is to introduce large numbers of Chinese into Hong Kong from China proper; to have them naturalised there as British subjects, and then to bring them here. By this means the £10 poll tax would be evaded; and it is quite possible that in this way a solution may be found for the vexed labour question. For our part, we would far rather see coolies brought here for plantation work, than hordes of Chinamen.

The *Maryborough Chronicle* estimates this season's crop of sugar on the Mary at 3,000 tons, and a like amount for Bundaberg. This will be a still further falling-off in the crop of the Maryborough district, which was 4,157 tons in 1881, and 3,570 tons this year. On the other hand it represents a large increase for Bundaberg, which turned out 619 tons in 1881, and 579 tons in 1882. Much damage has been done by the exceptionally bad frosts of last month, which affected the cane everywhere in the southern parts of the colony. Much of the young cane has been run through the rollers already, and the ground replanted, which will tend to increase the crop of 1884.

Bundaberg is progressing rapidly, and until the recent frosts the cane looked splendid. The damage done is more serious than it would otherwise be, owing to the absence of adequate machinery for dealing quickly with the frosted cane. A good many mill plants are in course of erection, or on order, and another year will find the planters better prepared for emergencies. Notwithstanding frosts and other draw-backs, we predict a bright future for this district.

Mackay seems destined withal to maintain supremacy as the sugar metropolis. Many foreign capitalists have invested here, and the cry is "still they come." About 20,000 acres were selected at the last land Court, and the demand seems to be increasing rather than diminishing. New machinery is going up in all directions, and the total acreage under crop, will in two years be perfectly astonishing. The greatest activity is observable at Homebush, Victoria, and Farleigh plantations. Timber is in great demand, and exceedingly scarce. Draught horses too are not to be had for money, and several of the newer selections are yet at a standstill for want of them.

As an instance of the curiosities of modern colonization, and the many sides it presents, we refer to the successful enterprise and ability exhibited by the Hop Wah Company of Chinese sugar planters at Cairns. We sometime since had occasion to notice some excellent cane sent to our office from that plantation, which was grown on forest soil. We now hear that crushing is being carried on most successfully there with first-class results, as much as three and a half tons being obtained per acre. The principal managers on this plantation are Chinese gentlemen of good social standing in their own nation, while the sugar boiler is a German. We may safely assume, however, that before long even that important position will be held by a Chinaman.—*Planter and Farmer.*

ORANGE TREE CULTIVATION.

The following facts as to orange cultivation at the Azores, communicated in a letter to an Australian contemporary, will throw some light on the causes of decadence in the tree and the means of preventing it:—

Until 1836 the orange trees budded, blossomed, and fruited with unvarying regularity. The grower would as soon have suspected the sun of variation from his diurnal course as the orangeries from their yearly round of duty. They were handed from father to son, and lasting as they did from generation to generation, it is not surprising that they became a symbol of permanence. These trees cost the growers no care, no attention, no labour, save the labour of picking and packing, so far as we can understand. The people might dance and drink the year round, and the orange would blossom and fruit the year round, without trenching, without manuring, without draining—it may be without pruning The plant was neither fickle nor fastidious, and the islanders rejoiced in their orange trees. Suddenly, however, there came a change. This bright picture of the growing, greenleaved, self-contained tree, surrounded by a joyful, sun-loving, dancing people, dissolves away, and gives place to a pale-leaved and sickly tree, surrounded by a carefaced and inquiring population. Their first proceedings were those of the panic-stricken; they were carried to extremes. From absolute indolence they rushed into alarming activity; but it was the blundering activity of ignorance. Having had little need to inquire into the physiology of the plant, or the relations subsisting between the soil and the plant, they adopted measures to set things rights which outraged both, and only made things worse; but gradually, by the aid of the suggestions of science and a teachable disposition, a middle course was hit upon, and restorative processes were prescribed with an intelligent knowledge of the patients' requirements.

At first the trees were overloaded with manure and stifled with shelter, and a great deal more was done to them than they could well bear. Now they perceive that thorough drainage is at the foundation of successful orange growing; that next to this, trenching to a great depth is essential; and thirdly, that manure must be applied—but with discretion. It is true the trees are more fickle than they were, and die more frequently, and the fruit will not keep so long. But growers can again count with tolerable certainty upon their crop. The disease of the orange was first discovered in the Azores in 1836, when it was found that the oldest and best trees—as much as 200 and 300 years old, and producing each 6,000 to 20,000 oranges—were disappearing. It was observed that all the trees affected produced a very heavy crop the very year that the disease manifested itself, that the leaves became yellow and fell off in great quantities, and on the trunks or stems near, and sometimes beneath the ground, the bark opened, and drops of a kind of yellow gum exuded. The drops resembled tears (*lagrimas*, in Portuguese), and therefore the disease was named lagrima.

Many orangeries were quite destroyed, and a remedy was eagerly sought. Opinions as to the cause of the disease

were much divided. Many thought it must be that the orange tree had a limited period of existence, and this being reached, the tree must thus naturally decay. As we then only propagated trees by layers, this explanation was not thought too unreasonable, but afterwards it was found that seedlings were attacked in the same way. Then it was found that superabundance of moisture in the soil was one of the worst conditions for the disease. Soon it was discovered that the destruction of the diseased bark and wood in the stem of the tree was the best method to save it. From February till August a skilled horticulturist visits every tree, and at the slightest sign of exudation of gum he cuts the bark across, to allow it to run out. If the disease is in an advanced state, the bark and the whole of the diseased wood is cut out, the roots being bared to a distance of a foot or two feet from the stem, every portion of diseased root being cut away. By this means the tree is cured if the disease is found at an early stage; if not, it is dug out, and a fresh tree put in from a reserve which is always kept for such contingencies. Although the disease still continues, the gardens now look very prosperous, for the remedy is known. . . . So we are returning to the old traditional culture. We are clearing the shelters, pruning the interior of the trees for the admission of air and light, are less liberal with manure, and keep the ground free of weeds, except when we want to excite vegetation. We have abandoned propagation by layers, and graft good chosen kinds upon seedling stocks. For shelter we prefer trees with their foliage, and take care not to let them grow too high.—*Land.* [The disease is clearly "canker."—ED.]

NOTES ON THE PHARMACY OF CINCHONA.

BY R. W. GILES.

It may be taken for granted that the members of the Pharmaceutical Conference are perfectly well aware of the contradictory and unsatisfactory state of the pharmacy of cinchona, for there has scarcely been a meeting at which it has not been pressed upon their notice, so that they may possibly ask "What is the use of this wearisome iteration?" The answer is that the grievance remains, and custom and prejudice are so inveterate that it is necessary to attack it again and again, even with the same weapons, before amendment can be hoped for. In this way alone pharmacists are able to exercise some influence upon their own Pharmacopœia.

All practical pharmacists must be aware that it is next to impossible to obtain officially recognized cinchona bark of the official alkaloidal standard; while there is no lack of barks of superior alkaloidal value and equally well adapted to pharmaceutical purposes which are not officially recognized. These evident truths have been asserted amongst others by Trousseau et Pideux (*Traite de Therapeutique*), Professor Fluckiger (*Pharmaceutische Zeitung*), and by Messrs. Umney, Holmes, and Dr. Paul, at meetings of this Conference.

The only dissentient that I know of is Mr. de Neufville, who asserted in a paper read at the last Conference (*Pharm. Journ.*, vol. xii., p. 369), that the *supply of flat* calisaya during the past few years had been abundant, and the *quality* of *quill* calisaya had been good; but I cannot put that and that together so as to amount to a statement that in his opinion there had been an abundant supply of good calisaya bark; and even then I should be obliged to conclude that the preponderance of evidence was against him.

Thus far the cinchona difficulty appears to be geographical; good barks, far exceeding the modest pharmacopœial standard, being excluded because they do not grow west of Greenwich and do not bear the name of calisaya. These do not appear to be distinctions of sufficient importance to place in opposition to scientific tests. Dr. Paul put the case clearly and conclusively when he said that an alteration was necessary in the range of selection of pharmaceutical barks; that South American barks should not be excluded, but that Indian barks should be admitted. In other words let alkaloidal standard be the sole test.

In consequence of the "fearful deterioration of calisaya bark,"* and the unsatisfactory state of its pharmaceutical preparations, cinchona has fallen more and more into disuse, to the prejudice of pharmacy and of medical practice, its place having been usurped by quinine, contrary to the opinion of the best authorities upon the relative value of the two medicines. It is the province of pharmacists to rectify this miscarriage amongst their wares, and to restore one of the most valuable articles of the materia medica to its proper place and functions. It is not suggested that they should substitute even good Indian bark for inferior calisaya, when the latter or its preparations are prescribed, however unadvisedly; but that they should take care to have in stock bark of sufficient alkaloidal value (independent of the B.P. standard, which is too low) and that they should *educate* the medical profession to the use of it.

Although therapeutics are a forbidden subject, it may be permitted to quote the opinions of orthodox authorities upon the therapeutical qualities of cinchona and its alkaloids as an indication of the direction which pharmaceutical research ought to take, the more so as those opinions show that the chemistry of cinchona has hitherto moved in the wrong direction.

It has been well established by the Medical Commission appointed by the Government of India to investigate the febrifuge properties of the cinchona alkaloids,* and their conclusions are supported by the testimony of English, and more especially of continental observers,† that the febrifuge and antiperiodic action of cinchona is common to *all* its alkaloids, and it follows that the exclusive employment of quinine, as it has long prevailed, is a wasteful mistake. But more than this, the best writers upon therapeutics assert that *cinchona* possesses medicinal properties superior to those of any or all of its alkaloids, which Dr. Pereira attributed in part to the astringent properties of the cinchotannic acid, and in part to the aromatic quality of the bark causing the alkaloids to sit more easily upon the stomach.‡ From this it may be inferred that pharmaceutical preparations of cinchona would be free from the objection sometimes charged against the mixed alkaloids employed in India under the name of cinchona febrifuge, that they excite nausea. In Neligan's 'Medicines,' similar opinions are expressed, viz. (p. 737): "Most practitioners are of opinion that none of the alkaloids possess the same medicinal properties as cinchona bark, *more especially in the treatment of intermittent diseases*...and... I must, however, confess that every day's increased experience induces me to prefer the preparations of bark to those of any of its alkaloids when a *tonic* effect is sought for."

Why then should "*most practitioners*" have so far changed their opinions, or at any rate so altered their practice, as to substitute quinine for cinchona almost universally, and particularly in those periodic diseases for which it is so emphatically asserted that none of its alkaloids possess equivalent virtues? Is it not, at least partly, because in the words of Mr. Umney already quoted, "Calisaya bark has deteriorated to a fearful extent of late," and, as Dr. Paul told the Conference last year, "it now really contains nothing more than a little cinchonine."

It may be very loyal to the Pharmacopœia to continue the unquestioning supply of calisaya bark which was described upon the same occasion as "almost invariably worthless," but how about the welfare of fever-striken patients, and the credit of pharmacy? It must not be forgotten that the Pharmacopœia never initiates anything; it is a codex of remedies which have already been approved and which it has become desirable to place under control.

The reputation of cinchona has once before suffered, at a very early period after its introduction into Europe, from a similar deterioration in the importations of South American bark. The early supplies brought over from Peru by the Count and Countess of Chinchon (1640) proved so effectual in the cure of fevers and agues that more orders were sent out than the Peruvian merchants could execute properly, and they sent back consignments of inferior barks, which proved worthless and brought the new remedy into temporary disfavour. This deception is as good a reason as any other for the name of Jesuits' bark which was conferred upon it at about this period.

* See *Pharmaceutical Journal*, vol. ix, p. 213.

* *Pharmaceutical Journal*, vol. ix, pp. 78, *et seq.*

† Pereira, vol. ii., pt. 132; Neligan, p. 736.

‡ Pereira, vol. ii; pt. ii., p. 137.

There was no quinine in those days, or probably the parallel with our present experience would have been complete; but having no substitute the common sense of the 17th century set an example to the science of the 19th. It discarded the worthless barks and supplied itself with others of suitable alkaloidal standard assayed by the fever test. In these days of practical science brokers sell and quinine makers buy cinchona bark on the basis of its alkaloidal percentage, ascertained by exact analysis. The pharmacist alone buys hap-hazard the "showy barks," often very poor in alkaloids, and hence known as "druggists' barks," which the quinine makers are only too happy to leave for him and the dealers only too pleased to get rid of, though for pharmaceutical purposes percentage of alkaloids is more than a relative test of value,—it is an absolute test of fitness.

The very reverse ought to prevail; the pharmacist should secure the first choice by being willing to give a better price than the quinine makers, who can only give the alkaloidal value, which is literally the intrinsic value of a part of its constituents. Under this system the pharmacist would get much better value for his money than he does now by buying a "showy bark destitute of alkaloids." I have heard of a time-honoured establishment, which I must not further particularize, buying several serons of calisaya bark at 3s. 6d. lb., which proved to contain not a particle of quinine and only a very small amount of cinchonine. Its assay value certainly would not have exceeded 6d. This is a sort of bark which should be left for the stores, whom it would exactly suit, and where no questions are asked.

The question then is "What standard should be adopted for the cinchona of pharmacy?"

First, it should be an alkaloidal standard, not a quinine standard.

Secondly, it should be a mean and not an extreme standard.

And, thirdly, it should be catholic, admitting barks from all sources without arbitrary geographical distinctions, which, originally intended as definitions, have now become irrational limitations.

At the Conference of 1878, Mr Umney spoke of East India bark containing 5 or 6 per cent of quinia as the future source of fine fluid extract, and, if of fluid extract, of other pharmaceutical preparations. Assuming him to have meant 5 or 6 per cent of mixed alkaloids, that would be a reasonable standard to insist upon,—say a minimum of 5 per cent, which holds a mean place between the extremes. I have computed the actual average of ninety-three lots offered on sale by the Dutch Government last year, and find that it is exactly 4·7 per cent. The highest quality reached 9·8 per cent, the lowest touched 1·2 per cent, giving a mean of 5·5 per cent. The mean of the two results is therefore 5·1 per cent.

It remains to be considered how this standard should be secured, for it is to be feared that pharmacists generally do not submit their purchases of cinchona to the pharmacopœial test, and it is as well to acknowledge that refined tests are not praticable in the pressure of daily business Mr. Holmes, probably having this difficulty in view, suggested that the wholesale druggists should be required to state the percentage of alkaloids in the samples they offer, but this is scarcely sufficient for the protection or for the credit of the pharmacist.

The same difficulty seems to have presented itself to Messrs. Squibb, of New York, who have endeavoured to meet it by publishing what they consider a simple, easy process of assay suited to the wants and the skill of well-trained pharmacists who are not expert quinologists. Whether the process possesses the desired qualities of simplicity and facility may be judged by perusal of the description at p. 77 of the third number of Messrs. Squibb's 'Ephemeris.'

In pursuit of a similar object I have been led to prefer the more simple hydrochloric acid process, which I tried on the recommendation of Dr. De Vry, in his laboratory at the Hague, and with the advantage of his assistance. The *modus operandi* finally adopted is as follows:—

Take 25 grams finely powdered cinchona bark, mix with 2·5 c.c. strong hydrochloric acid (=2·6 c.c. B.P. strength) in 30 c.c. distilled water, or just so much as suffices to moisten the bark; set by for two hours, add 100 c.c. distilled water and let stand for twelve hours or more, stirring occasionally, until all foam disappears from the surface. Pour into cylindrical glass percolator, the mouth of which has been stopped by a pinch of charpi loosely drooped into it and moistened with a little water, and recover the clear percolate. Pour on more water until the percolate ceases to be precipitated by caustic soda. In this way about 300 c.c. are recovered. Precipitate with caustic soda in considerable excess. Set the mixture by for twelve hours, when it will be found that the alkaloids have settled in a compact coherent stratum from which nearly the whole of the supernatant may be decanted. The decantate must be reserved. The precipitate is then poured upon a filter and washed with a little weak solution of soda to remove traces of cinchona red; finally it is washed with a little distilled water, the whole of the washings being added to the decantate and the measure noted. When the precipitate has drained it is to be carefully transferred to a tared procelain dish, dried over water-bath and weighed. The weight should not be less than 1·25 grams, corresponding to 5 per cent mixed alkaloids. But this will not be an exact indication of the alkaloids contained in the bark, as an appreciable quantity remains dissolved in the mother-liquor. Practically this may be estimated as 0·05 grams in 100 c.c., which should be added to the ascertained weight of the precipitate, and the sum multiplied by 4 gives a very close approximation to the true percentage, quite near enough for pharmaceutical purposes. When greater accuracy is desired the mother-liquor is treated with benzol, and the alkaloids are recovered by operations which it is not necessary to describe as they need not be employed in pharmaceutical assays.

The merit of the above process is its simplicity and facility of manipulation; the several stages may be set going as opportunity offers, and they proceed automatically without withdrawing the operator from other duties. Secondly, the results correspond with the amount of alkaloids which can be extracted in practical operations.

If it were not for the title of this paper there would be no reason for saying anything about the pharmaceutical preparations of cinchona. As it is, a very few words will suffice. It is notorious that they do not meet the demands of modern medical practice. Cinchona won its reputation by administration in the form of powder, it has lost it by the substitution of inferior preparations of inferior bark. The tincture, decoction and infusion of former generations have had their day and are becoming obsolete, never again to find favour with prescribers, pharmacists or patients. They are all too feeble in alkaloids for administration when the specific effects of cinchona are in question. Their qualities and their condemnation will be found in a paper by Mr. Ekin in *Pharm. Journ.*, vol. ix., p. 213. Nor can it be necessary to pour more obloquy upon the much abused fluid extract, which has never yet found a single defender. Its poverty and its wastefulness have been often told. The best that can be said for it is that when carefully prepared from barks of suitable quality (which does not mean barks rich in alkaloids) it possesses agreeable astringent properties associated with an unimportant amount of alkaloids which render it acceptable as a vegetable tonic, but it leaves the major part of the valuable and characteristic cinchona principles in the imperfectly exhausted bark.

Fluid extracts are the pharmaceutical preparations of the day. Their convenience commends them equally to the medical practitioner, to his patient and to the dispenser, and the demand for them is not likely to be diverted; but a fluid extract of cinchona, worthy of its name, is still a desideratum in pharmacy.

The President proposed a vote of thanks to Mr. Giles. He feared the present was not the proper occasion for going into any question as to what principles the cinchona bark owed its therapeutical properties to; their time would not suffice to discuss that, even if they had sufficient medical knowledge to do so; but several important pharmaceutical questions had been brought forward in the course of the paper, and those might very profitably be discussed.

Mr. Wellcome said the subject of supplying chemists with bark of definite alkaloidal strength for dispensing

and manufacturing purposes had been much discussed before, and he believed that some houses did offer to chemists with their bark an assay giving the definite alkaloidal strength. That was the custom of some houses in regard to opium, and he believed Dr. Squibb and others supplied the trade in America with barks with which he furnished assays. It appeared to him that that was one of the most important safeguards, and, while he thought it desirable that every chemist should be able to assay for himself the alkaloidal strength and to determine the amount of the respective alkaloids, it was hardly practicable that he should depend entirely on his own assays, and after all the guarantee of a respectable house would be the best general safeguard. As to the question of the strength that should be accepted as a standard for pharmaceutical preparations, some members of the Conference might remember that he strongly urged last year that the quiuine strength should not aloue be accepted, but that a definite alkaloidal strength of the various alkaloids should be the only standard. A bark which yielded two per cent of quiniue ought to be satisfactory for manufacturing pharmaceutical preparations, providing it contained a proper amount of cinchonidine, quinidine and cinchonine, say to make 5 per ceut total alkaloidal strength. Quinoidine was also very active, and some of the preparations most sold in the Tropics for checking fever and ague consisted almost entirely of that resin, which was by many cousidered a modified or uncrystallizable quinine.

Mr. Southall said he could quite confirm the difficulty which had been mentioned in regard to gettiug a reliable calisaya bark for pharmaceutical purposes. There was still a good ruu on the preparations of hark other than the extract and tincture. The decoction was very much ordered by medical men in his part of the country, and was more relied upon than either the fluid extract or tincture.

Mr. Hampson thought they would he more likely to reach the point the author aimed at of having an accepted standard quality of bark, or bark yielding a certain proportion of alkaloids, if there were a standing committee of pharmacists, and not a pharmaceutical committee formed by the Medical Council entirely. The Pharmaceutical Society ought to be legally recognized in all these matters, and if practical pharmacists held their proper position with respect to the National Pharmacopœia, these important changes or improvements would be sooner brought about. As it was, these changes came about in an indirect and slow manner, and improvements did not take place as fast as they should.

Mr. Ekin said he feared the medical men in Birmingham had made rather an unhappy selection, according to Mr. Southall's statement, for in the experiments he had made, which were referred to by Mr. Giles, he found the decoction was by far the weakest in alkaloidal value of all the officinal preparations.

Dr. Symes confirmed Mr. Southall's statement that the decoction was very largely used and very much relied upon by medical men; it was not peculiar to Birmingham.

The President said it would be seen from the remarks which had been made that they greatly needed increased activity in the promotion of therapeutical research, and it would be well if there were a society for this purpose formed by medical men having competent chemical and physical knowledge.

Mr. Giles, in reply, said he could not claim that what he had brought forward was new, but still it sometimes did good to repeat what was already known. With regard to the alkaloidal standard, Dr. Pereira pointed out that cinchona made its reputatiou as a febrifuge by the use of a species of cinchona which was not rich in quinine, but in which cinchonine largely prevailed, and this seemed to show that they had made a mistake in pinning their faith so much to the alkaloid which happened to be first discovered. Although recent investigations appeared to show that it was necessary to give cinchonine or quinidine or cinchonidine in larger doses than quinine to produce the same effect, there appeared to be no difference in the effects produced, and, therefore, it seemed to be a great waste to throw away that which might be recovered simultaneously with the quiniue. At all events it seemed to him that it was rather their business to support the pharmaceutical manipulation of things than the chemical. He had often been disposed to think that chemistry had been ridden a little to death, and that isolation of active principles had been carried too far.—*Pharmaceutical Journal.*

PINE APPLES.—It is evident we can beat the States in pine apples. The largest ever grown in Florida is said to have had a circumference of twenty-three inches, and weighed 8¾ lb. The *Gladstone Observer*, however, says Mr. Fisher, of that place grew one last year which turned the scale at 9 lb. Mr. Fingir of the Logan Road, recently sold one of 12 lb. weight and some slightly less.—*Planter and Farmer.* [We saw one in Colombo which weighed 13½ lb.—ED.]

LAVENDER.—Whether the present mode of cultivating laven-der (*i.e.*, growing it for four years only) is the best may be open to question, seeing how often old and large plants are covered with blossom. The *Gardeners' Chronicle* (p. 262) mentions two hedges of lavender, in the terrace-garden at Pusey Park, Faringdon, which are literally sheeted with blossom. The hedges are four feet or so in width, and make a free growth every summer, but they are cut back every September to a width of twenty inches or so, and break out again into profuse growth in spring.—*Pharmaceutical Journal.*

SOIL POISON.—"Nearly all soils contain iron; it is this that gives them their reddish color. But iron has two oxides. One of them, containing the least amount of oxygen, is soluble in soil water, and is therefore readily taken into the roots of plants. Copperas, or green vitriol, is composed of this low or protoxide of iron and sulphuric acid. On exposure to air for a time, this low oxide takes in more oxygen, forming what is called sesqui-oxide of iron, which is insoluble in water. The subsoil which has never been stirred to admit the atmosphere freely, contains the low oxide, and when first turned up, if sown or planted soon, the roots of the crops take in this poisonous soluble compound of iron, and are much injured, if not killed outright. Turn up a little of such sub-soils at a time, an inch or so each year; let it be exposed to air and frost for a few months, and it will become innocuous. The new elements of plant-food in this new soil, will even act as a useful fertilizer....." We accepted the explanation, acted upon it, and those old farms, deepened a little, year by year, have improved in productiveness. When visiting the old homestead two years ago, I found the average depth of the plowed land thereabouts was perhaps 9 inches, frequently 12 inches or more, and it yields double what it used to do, under the same culture except as to depth.—*American Agriculturist* [This sesqui-oxide of iron, to which Mr. Abbay attributed the poverty of patana soils, may be the cause of the "dying-off" of cinchonas.—EN.]

THE GROWTH OF AMERICAN TREES.—Some notes have been published on the native trees of the lower Wabash and White River Valleys, the result of long and careful observations, made by Mr. Robert Ridgway and other naturalists, upon the forest growth of Southern Indiana and Illinois. The region described is of special interest, for the forest is hardly surpassed by any other in the number of species of which it is composed, and the magnificent development attained by many individual trees. Nowhere, in fact, in the whole of Eastern America have as many large specimens of as many species been recorded as Mr. Ridgway found in the lower Wabash Valley. Nearly all the largest and most valuable broad-leaved trees are there found associated together, and in a single square mile of woods seventy-five species of trees, nearly all of the first class, were tabulated, being nearly as many as grow on the whole European Continent. By actual measurement thirty-four species were found to occasionally exceed 100 feet in height, while seventeen others, although not measured, were apparently at least 100 feet high. The tallest specimen measured, a tulip tree, was 190 feet in height, and individuals of ten other species exceeded 150 feet. Mr. Ridgway states that the numerous small prairies, which were common in the Wabash basin at the time of its first settlement, have been transformed into woodland, and the area of the forest has greatly increased of late years. Extensive woods of oak and hickory, more than 80 feet high, and with trunks nearly two feet through, are now growing on that was open prairie within the memory of some of the present owners of the land.—*London Times.*

PUBLIC AND BOTANICAL GARDENS JAMAICA.

(FORESTRY:—COFFEES—CINCHONA—COCOA (CACAO)—OTHER NEW PRODUCTS.

To Mr. D. Morris we are indebted for a copy of his elaborate and very interesting series of reports on the Jamaica Gardens and Plantations for 1881. The range over which the reports travel is wide and comprehensive, taking in forestry, as well as the various coffees, cacao, cinchona, &c. Coconut culture is touched on and the cause of the failure of these palms in a particular district, has a direct bearing on the question of Australian gums and cinchona. The coconut palms were destroyed by a beetle which originates in the "Big Thatch" palm, *Sabal Umbraculifera*, and passes to the coconut with fatal effect, the Big Thatch palm living on. Mr. Morris states:—"It seems as if, in this instance, a choice must be made between the Big Thatch and the coconut." But the work of extermination is deemed impossible. The difference with us is that the pest originating in the gums, is as injurious to those trees as to the cinchonas, &c., which they infect.

We place here an extract which is largely as true of Ceylon as of Jamaica:—

As already mentioned, it is evident that Jamaica must depend for its prosperity and success, almost entirely on the resources and products of an agricultural character. We have no large stores of timber, we have no minerals, we have no manufacturing industries, and we cannot hope to struggle successfully with other countries in the more advanced arts and sciences. We, nevertheless, possess a rich and productive soil, a salubrious climate, abundant springs and a vast extent of uncleared mountain land; and it is mainly on the due utilisation of these valuable natural resources that our prosperity must ultimately depend. Under these circumstances the chief aim of the Department has been directed towards bringing into notice the nature and character of such resources and to fostering and promoting any well-directed efforts for their utilization.

The position and prospects of several new industries, such as Liberian Coffee, Cacao, Tobacco, Oranges, Mangoes, Pine-apples, Spices, India-rubbers, Fibre-yielding plants, &c., &c., are carefully noticed with this view; and the success which has already attended these comparatively recent efforts would indicate that capital and energy are alone wanting to place the island in an important position as the source of most tropical productions.

From Dr. H. A. A. Nicholls, an esteemed correspondent at Dominica, supplies of Liberian coffee and lime seeds were received to meet the extensive demands which had arisen for these plants. From Mr. Ed. S. Rand, a correspondent at Para, was received a consignment of 300 fruits of the Para nut; and from Dr. Hansen, about 50 seeds of the much esteemed Sabucaia nut. From local correspondents, I have to acknowledge the receipts of the carob tree, *Ceratonia siliqua*, from Mr. William Lee, Administrator-General, which yields the Locust pods so extensively used in the manufacture of foods for cattle; specimens of Orchids have been received from the Hon. Col. Hackett Capt. Mainwaring, R.N., and Mr. Oscar Marescaux; several ferns from the Reverend John Thomson, Halfway-Tree; some Orchids and other plants from Mr. Ed. Braham, St. Ann's; a supply of seeds of Timber trees and palms from the parishes of Hanover and Westmoreland, contributed by Mr. De B. Spencer Heaven and Mr. B. S. Gosset; a plant of *Sarracenia purpurea* and various seeds from Nova Scotia, by Mr. Anthony Musgrave, jnr.; a quantity of lime seed from the Honorable L. C. Shirley; some sweet orange seed from Messrs. Wray and Nephew, Kingston, and 517 nutmeg seeds from Dr. E. W. Major, Bath. I have to express my thanks to these and other valued correspondents in the Island, for such exchanges and contributions of plants; and I would add that the Department is always glad to acknowledge such contributions and to reciprocate by exchanges of any new and valuable plants that may be desired.

Plants and seeds in the usual course of exchange have been received from the Directors and Superintendents of the following Colonial and other Establishments, viz:—

The Botanic Gardens, Ceylon.
W. Bull, Esq., Chelsea.
The Acclimatisation Society of Queensland.
The Botanic Gardens, Trinidad.
The Botanic Gardens, Mauritius.
The Botanic Gardens, Buitenzorg, Java.
The Botanic Gardens, Hongkong.
The Botanical Gardens, Calcutta.
The Department of Agriculture, Washington.
Sutton & Sons, Reading, England.
W. Paul & Son, Waltham, England.
The Botanic Gardens, Singapore.
The Botanic Gardens, Saharunapore, N. W. India.
The Botanic Gardens, Melbourne.

The total number of receipts during the year consist of 10 Wardian cases containing valuable economic plants; 12 boxes containing Cocoa, Liberian coffee, and 350 packages and bags of seeds.

In return, this department has forwarded 6 Wardian cases containing plants; 16 boxes containing seeds and orchids, and an aggregate of 420 packets of seed weighing 107 pounds.

Exchanges and the free distribution of seeds and plants in the Island have received special attention. Nearly 400 packets containing seeds, &c., have been distributed by post among the Custodes of the several parishes and other correspondents in different parts of the Island. These packets contained seed of selected fruit trees, best Havannah Tobacco, Para-nuts, Gram or Chick Pea, Liberian Coffee, Cacao, Nutmeg, Cinchona seed, Ornamental and Timber trees, food plants, new grass seed, &c., &c.

I am glad to find that, by these means, I have been able to distribute and establish throughout the Island, many new and important plants, and the gentlemen who have kindly assisted me in thus reaching even the remotest localities, deserve the best thanks of the community.

I would here remark that there is much activity displayed even by the poorest peasants in obtaining and cultivating new plants; and I cannot but hope that, before many years have elapsed, this activity will result in the greater prosperity and wealth of the Island, and in placing it in the first rank as exporter of fruit and raw materials to the markets of England and America.

Sales of Economic Plants.—The local demand for economic plants has, in some cases, been quite beyond the resources of the Gardens, whilst in others they have been greatly taxed to meet the requisitions made upon them. The distribution of plants from each establishment will be given later on, but I would here remark that the distribution of plants, on payment during the past year has included 84 ounces of seed, 330,000 seedlings and 50,000 plants of Cinchona from the Cinchona Plantation; 40,000 plants of the best Trinidad Cacao, Liberian Coffee, selected Oranges, Nutmeg, East India Mangoes, Cardamoms, Vanilla, Clove, Cinnamon, Pine-apple suckers, and newly-imported Sugar Canes from the Castleton Gardens and Hope Plantation, and numerous packets of miscellaneous seeds and cuttings. This distribution is in excess of that of last year by nearly 12,000 plants; and it is gratifying to find that, notwithstanding the fact that certain prices are now charged for plants formerly given away, the number of plants distributed is steadily increasing. The receipts on the sale of plants during the past year amounted to £700 3s. 6d.—the total receipts, together with the results of Cinchona Bark and Jalap sales, amounted to nearly £3,400. The provision on the estimates for the total cost of the Department for last year was nearly £5,431. Not being a Revenue Department, the acquisition of extra receipts is by no means looked upon as a main feature in the administration of the Department. Its chief objects are of a scientific and industrial character, viz., to assist and foster in every possible manner the introduction of new economic plants into the Colony; to propagate and distribute such plants throughout the Island, supplying at the same time whatever scientific and practical information that may be desired respecting their successful utilization and culture.

Diffusion of Information respecting Economic Plants.—A list containing the names of the most interesting timber and shade trees, ornamental trees and shrubs, fruit

trees, economic and medicinal plants, palms, ferns, orchids, etc., which are kept ready for distribution at the Gardens was published as an Appendix to my Report for 1880, and I am glad to find that it has been the means of stimulating greater attention to the resources of the Department and has resulted in a much larger distribution of plants. Various papers bearing on the cultivation of Cinchona and other plants have been prepared and published, and a large correspondence undertaken with the view of disseminating information in the Island respecting the treatment and cultivation of new plants.

Amongst the papers prepared and distributed last year were a revised edition of "Hints and Suggestions for raising Cinchona Plants from seed and establishing Cinchona Plantations"; copies of a valuable report giving the "Results of analyses of Jamaica grown barks," by Mr. John Eliot Howard, F.R.S., "Hints on planting and establishing timber trees, ornamental trees and shrubs, fruit trees, etc., and the conditions under which they might be obtained from the Public Gardens." "Hints and Suggestions for the improvement of the Coffee industry in Jamaica"; an "Estimate of the cost per acre of establishing Cinchona Plantations on the Blue Mountains"; a "List of Economic Plants offered by Government for distribution in the Island," and copies of a lecture delivered by the Director at the request of the Institute of Jamaica on "Some objects of Productive Industry."—Parts I and II.

CASTLETON GARDENS.

The portion of the Experimental Garden set apart for the cultivation of Trinidad Cacao has been drained by a series of open main and tributary drains, amounting to four hundred and twenty-nine feet long by from eighteen to twenty-four inches wide and deep.

Two thousand and seven miscellaneous trees and shrubs have been planted in various parts of the grounds, the majority of which being of an ornamental character were placed for effect in the rather bare portions of the old flower garden and shrubberies, and also to complete as far up as the main entrance, the shrubbery lying parallel to the public road in the Experimental Garden."

A new plantation consisting of thirty-nine nutmeg and ten clove plants has been made close to the aqueduct at the foot or lower edge of the mule pasture. The plants are all growing nicely.

Eighty-four plants of the best Trinidad varieties of Cacao have been put out partly in the old plantation in the ravine, above the tanks, and partly forming a new plantation near the foot of the ravine adjacent to the official residence.

One hundred and eleven plants of Cacao, consisting of about equal numbers of the best six varieties cultivated in Trinidad have been added to the plantation in the Experimental Garden. Here it was found necessary to plant two hundred banana, sixty castor-oil bean, thirty guango and six *Erythrina umbrosa* to shade and otherwise protect the Cacao plants.

The exposed roots of the plants have been well covered with good soil brought from other parts of the estate, and all plants so treated now show a marked improvement on their previous condition.

CINCHONA PLANTATIONS.

The Establishment buildings having suffered severely by the hurricane of August, 1880, it was found necessary to rebuild or repair the greater number especially of the older buildings. This work was carried on by Mr. Ed. Scott Barber of the Public Works Department, and has resulted in a substantial and convenient set of Establishment buildings. The chief works effected were: general repairs to the propagating houses; rebuilding herbarium, and offices for clerk and superintendent; rebuilding tool shed and potting house; rebuilding upper and lower barracks; new shutters and internal repairs to Director's residence; a new back verandah; rebuilding stable and outhouses, and new shutters and general repairs to the Superintendent's cottage. The buildings, entirely new, which did not come under hurricane damages were, a store-room for Cinchona bark, and a small room as extra barrack accommodation; these were built by private contract. Most of the new buildings at present require re-painting and furnishing with gutters, and I am glad to find that a provision has already been placed on the current year's estimate for this purpose, as well as for rebuilding four plantation sheds, blown down, but not included under hurricane damages.

The tanks upon which the supply of water for the nurseries and propagating houses depends are in good order. The new tank built last year, as well as the old tank, lately repaired, require to be fitted with pumps, both for the sake of conveniently getting water, as also for protection in case of fire.

I have already suggested for the latter purpose that one of the pumps be a good force-pump capable of throwing a jet of water over the residence and most of the establishment buildings in its immediate neighbourhood.

While the establishment buildings were being rebuilt, advantage was taken of the circumstance to place them in more convenient situations, and to form a series of terraces with turfed slopes, so that they might be protected from the prevailing winds and be well drained. These slopes are now in good order, and they greatly add to the neatness and general appearance of the place.

With regard to the operations on the plantations, they may be conveniently summarized under the following heads:—

Nurseries.—In fulfilment of the promise made in my last Annual Report, special attention has been devoted this year to the establishment of suitable nurseries on each plantation, from whence a supply of strong healthy plants might be obtained for distribution, as well as for supplying and establishing land already cleared. The nurseries attached to the establishment buildings have been well maintained, and at present they contain 60,000 plants of *C. Officinalis* ready for distribution; 8,000 Hybrid; 5,000 *C. Calisaya*; 3,000 *C. Succirubra* and 2,000 *C. Officinalis var. uritusinga*. Most of the Hybrid have been raised from cuttings as also about 5,000 *C. Officinalis*. In the propagating houses and frames are also about 20,000 *C. Ledgeriana* raised from seed received from Java and India.*

On the Latimer Plantation a large nursery has been established containing about 80,000 plants of *C. Officinalis* which will be ready for distribution in May next; while at the Bellevue nursery there are 15,000 plants of the same species intended for supplying the vacancies on the plantation in its immediate neighbourhood. The total number of plants in the nurseries at present may be summarized as follows:—C. Officinalis, 155,000; C. Officinalis var *uritusinga*, 2,000; C. Hybrid, 8,000; C. Calisaya, 5,000; C. Succirubra, 3,000; C. Ledgeriana, 5,000.—Total, 178,000.

These numbers are irrespective of the plants distributed during the past year which amounted to 330,100 seedlings and 48,967 plants, while 124,623 plants were put out on the plantation themselves.

The distribution of seeds and plants for private plantations on sale were as follows:—

	Seeds.	Seedlings.	Plants.
C. Officinalis ...	58¾ ounces	215,800	48,252
C. Succirubra ...	24½ ounces	102,300	662
C. Hybrid ...	½ ounce	12,000	53
Total...	83¾ ounces	330,100	48,967

Upper Bazza Plantation.—The operations at this plantation have been confined to weeding and cleaning plants established in 1879 and 1880, and supplying vacancies. The number of plants put out amount to 66,889 *C. Officinalis*, 4,747 *C. Succirubra*, and 3,420 *C. Hybrid*. All these plants are doing well at this elevation, 4,800 feet to 5,400 feet, and the plantation, containing about 50 acres, and an aggregate of 120,000 plants is well established and in good order. Although the plants are only a little over 2 years old, they are, in many cases, between 5 feet and 6 feet high, and being planted 6 feet by 6 feet give a uniform and unbroken appearance, which is in marked contrast to the portions of the plantations formerly planted with trees at 10 feet and 15 feet apart.

Not only do the trees when closely planted† cover the ground more quickly, and save considerable expenditure in weeding, but they stand wind much better, and produce straight clean stems of great value as regards yield of trunk bark.

* As these remarks relate to circumstances more than nine months ago, it must be understood that the resources of the nurseries, and, indeed, of the Plantations generally, at the present time (Sept. 1882) are considerably altered. [Note added.]

† We do not call 6×6 closely planted.—ED.

White's Piece.—This small plantation of about 10 acres was formerly planted with *C. Succirubra* and the Hybrid variety. All the trees between 10 and 11 years old were either "uprooted" or "coppiced" during the year 1880. The "coppiced" stumps, of which about 200 threw up strong shoots, are doing well. The latter, now about 18 months old, are about 4 feet high and in strong health. The portions of the plantation from which trees were uprooted, after being carefully cleaned and trenched, have been replanted with 28,870 plants of the Hybrid variety at distances of 4 feet by 4 feet. The results, so far, fully justify the opinion I have already expressed, that land from which crops of Cinchona have been taken will, if properly treated, be quite capable of producing subsequent crops of the same kind.

Belle Vue Plantation.—This plantation is in course of being replanted with the best kinds of Cinchona to replace the poor wind-blown specimens of *C. Succirubra* which were planted here about four or five years ago. Among the new species already established are 1,485 plants of *C. Ledgeriana* raised from seed received from Ceylon, 7,534 plants *C. Calisaya* of the Jamaica plantations determined by Mr. John Eliot Howard, F.R.S., 11,678 *C. Officinalis var Uritusinga* from the Government Plantations, Southern India, and 3,500 of *C. Officinalis*, stated by Mr. Howard to be the *Colorado de Loxa* of Spanish commerce, The total number of plants put out being 24,197.

The other plantations are in good order and well established, the chief operations upon them have consisted in keeping them clean, maintaining the roads in good order, and in harvesting the successive crops of seed and bark. While on the subject of seed, I may mention that the large quantities of the seed of the best forms of *C. Officinalis* produced are more than sufficient to meet local demands, and in the event of the extension of private plantations in Jamaica, there will be no difficulty in meeting any requisitions that may be made for seeds of this valuable bark.

The trees of *C. Succirubra* are still yielding but poor supplies of seed, and I am obliged to depend on the plantations of India and Ceylon for this kind.

The seed of such valuable kinds as *C. Hybrid*, *C. Calisaya* and *C. Ledgeriana* are not distributed at present, but well grown seedlings in boxes are supplied at such moderate rates that, while there is the minimum amount of loss in raising them, they are placed within the reach of all who desire to add these species to those already under cultivation.

Introduction of New Kinds of Cinchona.—The chief event of the past year in connection with the Cinchona Plantations has been the successful introduction on a large scale of the valuable *Cinchona Ledgeriana*, which is, admittedly the most precious of all the known species of Cinchona.

A small quantity of seed of this kind—weighing less than ½ oz.—was received from the Government of Netherlands India in April last. From this seed 14,437 seedlings were successfully raised and pricked out. These were subsequently transferred to bambu pots and to well protected beds in the nurseries. I regret, however, to report that latterly, in spite of the great care taken with them, many of these plants have given signs of "going off" in an unaccountable manner, and it is very probable that only about 6,000 or 8,000 will be ultimately ready for planting out in the fields. Fortunately, however, further supplies of seed have been received from Dr. King and through Sir Joseph Hooker, so that before the end of the present year fully 30,000 plants of *C. Ledgeriana* will be established in the island. The three fine plants of *C. Ledgeriana* received through Kew, from Mr. John Eliot Howard, F.R.S., mentioned in my last Report, have done remarkably well, and they have fully proved the suitability of both the soil and climate of Jamaica for the successful cultivation of this bark. The largest plant, now two years old, is 5 feet in height and with a girth at the base of 6 inches. From these plants about 40 cuttings have been established with every promise of the number being considerably increased. Seed of *C. Calisaya var Josephiana* was received from Dr. Trimen, Director of the Royal Botanical Gardens, Ceylon, and about 60 plants are ready for planting out.

The plants of the hard Carthagena bark presented by the Secretary of State for India, in 1879, are doing well at an elevation of 5,500 feet, but I believe that they would do better at a still higher elevation. The habit of growth of these plants is remarkably robust, and they promise to be very suitable for sheltered spots at the highest points at which cultivation can be carried on on the Blue Mountain range.

Seeds of several valuable species of Cinchona from the Southern India Plantations have been received from Lieut.-Col. R. H. Beddome, Conservator of Forests, Madras Presidency. In the letter which accompanied the seeds, Lieut.-Col. Beddome refers to them as follows:—

I send you, by post, 6 oz. of seed of *C. Officinalis var uritusinga*, 4 oz. of seed of the *glabrous* variety of *C. Pubescens* (Magnifolia) and ¼ oz. of seed of *C. Pubescens*.

The seed labelled "Magnifolia" is one of the varieties and species first called "Hybrid Pubescens" by Mr. McIvor and afterwards "Maguifolia," but has nothing to do with *Cascarilla Magnifolia* except a similarity in leaves. It is very highly reported on and yields a large percentage of Quinine. Its growth is most robust between 6,000 and 8,000 feet on these hills. Little is known of it yet except that its yield of Quinine is very good. It grows here well on poor grass land soil where *C. Succirubra* will not do.

Mr. Robert Cross, who is here, calls it the true Pata de Gallinazo of Chimborazo (Markham, Peruvian Bark, 1880, p. 219 n.) and says that he collected the seed there and sent it here originally.

C. Pubescens is very similar to this in habit, &c., but has the leaves pubescent underneath.

Analysis of Jamaica-grown Barks.—With a view of accurately determining the botanical classification, as well as the commercial value of the bark yielded by the different kinds of Cinchona trees under cultivation in Jamaica, I made a complete collection, containing eight sets of specimens of leaves, flowers, fruit, as well as one pound by weight of Cinchona bark, from every distinct form or variety which had come under my notice here.

This collection was forwarded in June last to Mr. John Eliot Howard, F.R.S., who is believed to be one of the highest living authorities on Cinchona and Cinchona Barks. I asked Mr. Howard to be so good as to compare the botanical characters of the specimens sent from Jamaica with those in his large collections from South America, India, and Ceylon, and I furthermore ventured to ask him to obtain for me a quantitative analysis, with the probable market value of the various samples which accompanied them.

A summary of the valuable information supplied by Mr. Howard was lately published in the Jamaica Gazette, and there is no doubt that this authoritative and exhaustive report will prove of the greatest service to those interested in the cultivation of Cinchona in Jamaica.

One of the chief points brought out by Mr. Howard's report is the existence on the plantation of true yellow bark trees, which had hitherto been included as forms of the Crown bark *C. Officinalis*.

These trees had attracted my notice from the first, and I took steps immediately, on my arrival, to keep the seeds separate and to propagate them for supplying steep and windy slopes, for which they appeared to be admirably adapted.

These trees are no doubt the produce of the Calisaya seed which the late Superintendent had received from India, but, owing to some mistake, the robust "Hybrid" kind had for many years been adopted for the yellow-bark trees, and had consequently received much attention on that account. In reply to questions addressed to Mr. Howard respecting the true yellow bark trees, he supplied the following analysis of trunk bark, viz.:—

Quinine Sulphate.	Quinine Alkaloid.	Cinchonidine.	Cinchonine.	Quinidine.
4·93	3·70	0·60	0·35	0·05

and added "Specimens marked No. 1 and No. 2 appear to me to be true to the Calisaya type, and form a valuable portion of the Plantation. I should not think that they belonged to either of the *Josephiana* or to the *Ledgeriana* form, but that the exact variety is perhaps not yet published. In the meantime it may be well to call them *C. Calisaya* simply.

"There is no appearance of hybridity, nor any resemblance to the Loxa (*C. Officinalis*) barks."

As corroborating, in a singular manner, Mr. Howard's

determination of these trees, I have just received a letter from Mr. B. C. Moens, Director of the Government Plantations in Java, in which he refers to them as follows:—

"The specimens of *Calisaya* 1 and 2 came duly to hand. They are very like the best forms of what we call *C. Calisaya Javanica*, and which are the *C. Calisaya vera* of Weddell.

"From *C. Ledgeriana* it differs by the large flowers—which I think were red—and the larger fruits, and by having the leaves more obovate, at least, with the greatest breadth above the middle of the leaf—whilst the leaves in *Ledgeriana* are more oblong—elliptical. That it is a *shrub* with you, will be due to the high elevations at which it is planted. I would advise to try it at 3,000 feet in a good locality, and think that you will see *trees* grown from the seed of No. 1. The bark is a very good one, and gave by analysis 5·38 per cent of quinine, 0·12 of quinidine and 1·12 of cinchonine and amorphous alkaloid, a very rich material for quinine manufacturing. If they come true to seed, they will beat *Officinalis* with you, like *Ledgeriana* does with us, and I am sure you will find that they will do better at a lower elevation."

These trees, consisting now of about 100 specimens in fruit, will supply a valuable means of establishing this desirable kind in Jamaica, and special care is being taken to preserve the seed as it ripens and to utilize it to the greatest extent.

The "Hybrid" variety is believed by Mr. Howard to resemble *C. Officinalis var uritusinga*, but as we have plants of this latter kind both from India and Ceylon, a careful comparison will soon be possible, so that the point can be definitely settled. The so-called Hybrid is a hardy plant and a remarkably free grower, and for general planting purposes is as valuable as any.

Mr. Howard's analysis of the trunk bark of the Hybrid variety is as follows:—

Quinine Sulphate.	Quinine Alkaloid.	Cinchonidine.	Cinchonine.	Quinidine.
8·00	6·00	0·73	0·10	0·03

As mentioned in a former section a plantation of nearly 10 acres containing 28,870 plants has been established entirely with this kind, and 3,420 plants have been put out on the Buzza Plantation, so that its permanency as a cultivated plant in Jamaica is well secured. With regard to Mr. Howard's other analyses, a refereuce to the Report will afford many interesting proofs that both the Crown and Red Barks under cultivation here are the best of their kinds, and that their produce compares favourably with that of other countries.*

Bark harvested during the year 1881.—Only one shipment of bark was made during the past year. The weight represented 14,397 pounds of dried bark which realized prices ranging from 7s. 8d. for trunk bark to 1s. 6d. for twig bark. The net result of the shipment was £2,675 6s. 9d., which, with the proceeds of the sales of 1879-80 represents a total value of £8,167 1s. 8d. of bark shipped within 15 months. Full particulars respecting the qualities and prices of bark shipped during the past year have been already published.

Extension of Cinchona cultivation in private hands.—There are encouraging indications that Cinchona planting is being taken up generally by private enterprise, and as shewn above, the distribution of seeds and plants from the Government plantation has assumed considerable proportions. This has been due entirely to the encouraging results of the late sales of bark and to the liberal terms on which facilities for embarking in Cinchona cultivation are afforded by Government. Grants of land suitable for Cinchona are offered under conditions which practically place the Cinchona planter in Jamaica in a most favourable position. The supply of seeds and plants, especially of the valuable Crown bark, *C. Officinalis*, is such, that no difficulty is anticipated in meeting any demands that may arise under this head.

Weather Observatory.—With the assistance of Mr. Maxwell Hall, M.A., F.R.A.S., a weather observatory has been established at the Cinchona Plantation at an elevation of 4,900 feet. This is believed to be one of the highest stations in the British Colonies and it is intended to work it in connection with Mr. Maxwell Hall's other stations in Jamaica and publish the results as a monthly summary in the Government Gazette. The instruments have all been carefully compared with standards and fitted with Stevenson's screens, &c., &c., in accordance with the methods usually adopted at such stations. The readings are taken daily at 7 a.m. and 3 p.m. A tropical rain gauge and a self-registering maximum and minimum thermometer have also been placed on the Blue Mountain ridge at an elevation of 6,000 feet. These are regularly visited three times a week.

Apart from the bearing which such observations must have on the selection of lands for Cinchona cultivation, it is hoped that the observations at this station will contribute to the success of the important work in which Mr. Maxwell Hall is engaged, and afford information of a scientific and general character concerning the climatology of the British West Indies. The average readings of the Barometer at this elevation are 25·350; the average annual temperature 63° Fah.; the average annual rainfall (on readings for 9 years) 124 inches. During the hurricane of August 18th, 1880, the lowest observed reading of the Barometer was 24·50; while in that of November 1st, 1874, it was 24·75.

The heaviest rainfall during the past year fell on October 5th-6th when 13 inches were registered in 24 hours. This would represent a fall of 1,315 tons of water per acre—a circumstance which easily accounts for the damage often done by heavy tropical rains to delicate plants in beds and nurseries, and moreover is an element which Coffee and Cinchona planters would do well to consider when "hoe-weeding" and "scraping" and "no drains" are the normal modes of cultivation.

---

* *Remarks on the Annual Report for 1880, on the Government Cinchona Plantations, Jamaica, by Mr. John Elliot Howard, F.R.S., &c.*

The tenor of this Report shews, in my opinion, that the circumstances of climate or soil must be more favorable in Jamaica than in India. The spontaneous growth of Cinchona, especially of the Crown Bark by self-sown seedlings, now literally forming patches of Cinchona forests on the Blue Mountain slopes (p. 7) is especially to be noted, as compared with the following statement in "The Cinchona Planter's Manual," by T. C. Owen, Colombo, 1881:—

"Be the evil what it may (that it lies directly in the soil, and in particular conditions of the soil not difficult to determine, there is little doubt) it is certain that the proportion of failures amongst Cinchonas of all ages is so large, as to be quite unparalleled in any other enterprize."

The specimens of bark sent are very carefully gathered, and represent apparently a higher produce in alkaloids than could be expected from the average.

It is very evident that the so-called "Hybrid," No. 4, if only it is a free grower, must be about the most valuable of all the sorts.

The price obtained in commerce does not seem proportionate to its value, but possibly, as remarked (p. 7) it may be an exceptionally fine specimen. So far as I can judge by the Botanical specimens it is a true form of *C. Officinalis*.

The large-leaved Crown Bark seed received from Dodabetta, must evidently be the *Uritusinga* of Pavon, the former defined by Sir Joseph Hooker. This is also an excellent sort to cultivate.

The designation "*var Condaminea*" is misleading, being used vaguely in India, and not at all recognised in trade. That which you term "the general type" of *C. Officinalis* appears to me to be the *Condaminea* of Humboldt, as reprinted in the Plantes Equinoctiales; but there are two forms included in Humboldt's plate. I refer to the more striking one.

The original names should I think be kept as far as possible. Sir J. D. Hooker has done well in restoring *C. Officinalis*, but as you see I use this term more widely than Sir J. D. Hooker. Your No. 4 is as true *C. Officinalis* as is the *Uritusinga* and differs only in the appearance of the bark.

La Condamine, who journeyed through Loxa in 1737 was the first to describe the Loxa Bark and figured it in Mem. de l'Academie des Sciences in 1738.

His representation is copied in Woodville's Botany, vol. 3. It is distinctly the *Uritusinga* form of leaf and accords well in the ovato-lanceolate form of the larger leaves with my plate of the *Uritusinga* in the "Nueva Quinologia."

Humboldt gives this character in his work *Uber Die China.*—*Walder, &c.*

C. Condaminea...foliis ovato-lanceolatis utrinque glaberrimis, and adds p. 21. 2nd Abschitt.

Since only one species bears expressly the name *C. Officinalis*, it must be the *tree* which yields the *Cascarilla fina de Uritusinga*—a fever bark which was considered the most useful in tertian fevers, &c.

Hence we see that the *Condaminea* is the same as the *Uritusinga*.

Your No. 4 is the *Condaminea* with a slightly different bark, but I should retain the term *C. Officinalis* for the *whole*, and the earliest names *Uritusinga*, &c., for the *forms* (I do *not* call them varieties).

Very likely your No. 4 is that from *Ayavaca*, but this is only a *guess*.

Your "ordinary quality" is *C. Officinalis—form* of Humboldt's plate.

The average annual and monthly rainfall taken at the Cinchona Plantation for nine years are as follows:—

RAINFALL RETURN, CINCHONA PLANTATION.

Month of	Year ending Sept. 30, 1873.	Year ending Sept. 30, 1874.	Year ending Sept. 30, 1875.	Year ending Sept. 30, 1876.	Year ending Sept. 30, 1877.	Year ending Sept. 30, 1878.	Year ending Sept. 30, 1879.	Year ending Sept. 30, 1880.	Year ending Sept. 30, 1881.	Monthly Average.	Remarks.

Average Rainfall, per annum, during nine years, 12·14 inches.

PALISADOES PLANTATION.

The Superintendent's house, store room and outbuildings are in good order; the watchman's hut blown down by the hurricane at the western end of the plantation still requires to be rebuilt, and a vote for the purpose has been placed to the credit of the Public Works Department.

This plantation—which is maintained as an experimental coconut plantation for the utilization of waste lands near Kingston—is slowly recovering from the effects of the cyclone, and is now being considerably improved under the care of Mr. W. Mowat, who has had a large experience as a tropical planter.

The yield of the plantation during the past year represented a crop of 75,000 nuts, or a total return of £250 15s.,* while the cost of upkeep for the same period was £318 4s. 0½d. The trees on the plantation are still, however, in a young state, only about one-fifth being in bearing. Out of these, owing to the combined effects of the cyclone and drought, probably only one-half yielded an appreciable crop of fruit. The effects of the drought were most felt by the young plants, and as it was found impossible to supply them all with water, a large number was lost. In fact, the entire run to the western side of the light-house both in old and young trees suffered most severely: very few nuts were gathered while the trees themselves required the utmost care and attention to keep them in good health. During the hurricane the sea washed completely over this portion of the plantation into Kingston harbour, carrying away the sand, leaving the roots of the Palms quite bare and exposed to the intense heat of a tropical sun. Considerable effort has been made to overcome these injurious conditions by recovering the roots with soil, &c., and shading them with dead fronds and weeds. The Superintendent reports that the trees are fast improving under this treatment, and throwing out strong healthy spathes, with every prospect of a good crop for 1882. For young coconut plants put out in such hot arid districts as the Palisadoes, it is found necessary to dig holes 3 feet wide and at least 3 feet deep; a good supply of manure is mixed with the sand and soil, and placed at the bottom of the pit. The young plants require also to be well mulched and regularly watered till they are established, and an annual supply of manure with an occasional sprinkling of sea water is found most beneficial. Under this system it is anticipated that the trees will come into bearing in five or six years, and the produce should not average less than 50 nuts per tree.*

In connection with the bearing of coconut trees I may mention that I have found it difficult to obtain reliable information as to the value of coconut trees in Jamaica. Owing to the facilities afforded by the markets of the United States and Great Britain, there is a great and increasing demand for coconuts all the year round. They seldom sell locally for less than 50s. or 60s. per thousand while in times of scarcity, like last year, the produce at the Palisadoes plantation, for instance, has readily obtained 70s. per thousand. At say 60s. per thousand, trees bearing at an average rate of 50 nuts per tree would represent an annual value at the rate of 3s. per tree. The general impression in Jamaica is that a coconut tree is worth "a dollar a year." In some cases this may be somewhat above the mark, whereas in favourable districts, such as Morant Bay and others, bearing trees may yield on an average as high as 100 nuts and be worth 6s. or even 8s. per tree. A coconut plantation in Jamaica, well established and in full bearing (say at the end of 8 years, with 60 trees to the acre and yielding an average of 40 nuts per tree) may be safely assumed to be worth at the rate of from £8 to £12 per acre—much, however, depends on the locality and the care taken to harvest the produce. The cost of establishing a coconut plantation till it comes into bearing cannot be more than £8 per acre.†

Copra.—Owing to the general injury sustained by the young nuts just forming on the trees at the time of the hurricane, a large number was expected not to mature into full and well-developed nuts. All that ripened and attained full size, amounting to 75,000 nuts, were sold at prices varying from 65s. to 70s. per thousand.

In view, however, of utilizing the nuts that were unsuitable for market in the green state, at the suggestion of His Excellency the Governor, they were all carefully picked out, and after being opened, the kernel was cured in the sun and so formed "Copra,"—a material commercially in great demand on the Continent for the purpose of making coconut oil. As no attempt had hitherto been made to test the value of Jamaica "Copra" in the London market, a shipment of 28 bags containing 1½ tons of Copra was recently made, which realized at the rate of £15 per ton. The brokers remarked: "The quality of "the Copra is good. . . It is used on the Continent "for making coconut oil, as there is an import duty on "the oil and none on the kernel. After the oil is pressed "from it, the refuse is used for feeding cattle and sells "at £6 per ton. If good quality is sent home, there is "a large business to be done in it."

* This return does not include £20 12s. 3d. received for 1½ tons of "copra": nor the value, estimated at £10, of coconut plants supplied to the Admiralty at Port Royal and the Department of Royal Engineers for planting on lands under their charge.

* Instead of getting indifferent manure from Kingston, it has been found more economical, as well as more satisfactory for the plants, to utilize the rich black soil and the vegetable refuse such as turtle grass, &c., found in the ponds on the plantations. A liberal application of these substances to both old and young trees is producing very marked results.

† As results of observation at the Palisadoes plantation it appears to take about 6 to 8 months to raise plants from seed nuts. If kept quite moist, and buried in shaded nurseries, they will sometimes only take 5 months before they are ready to be planted out. From the time the spathe bursts till the nuts are mature and full, a period of generally from 9 to 10 months elapses.

As an experiment, undertaken in the interest of proprietors of coconut plantations, the results are worthy of notice. Placing the value of the nuts at 40s. per thousand and 5,500 nuts to the ton of copra, this would give £11 as its first cost per ton. To this must be added cost of preparation and shipping expenses, which would be not less than £5, hence with coconuts at 40s. per thousand, the cost of placing a ton of Copra in the London market would be about £16. At the present high price of coconuts it is certainly more remunerative to sell them as they are; but should the price of coconuts fall below 40s. per thousand, it would be better to make Copra and ship the produce in that state. In the Pacific Islands and other places remote from good markets for fresh nuts, the manufacture of Copra has become a large and important industry. The extension of coconut plantations in Jamaica may therefore be undertaken with every confidence that they will prove of a thoroughly remunerative character, and this, it must be noted, without any reference to the coconut husk, which, with suitable machinery, might in itself form the basis of an important industry.

Coconut Disease in St. Elizabeth.—In a note on the distribution of the coconut in Jamaica, I lately made some observations with regard to what has been termed the coconut disease in the Parish of St. Elizabeth, which may be noticed here.

It has been remarked as somewhat strange that while the coconut palm grows freely everywhere along the coast of Jamaica, it is almost entirely absent from Alligator Pond to Black River, and indeed along the Southern Coast as far as Sav.-la-Mar. At first, this was taken as an accidental circumstance; but careful enquiry on the spot has convinced me that although the soil and climate differ very slightly from those in other portions of the Island where the coconut thrives luxuriantly, all efforts to establish it along the sea-board of the Parish of St. Elizabeth, and especially in the Pedro district, have signally failed. The plants appear to thrive for a few years and to grow remarkably well, but before coming into bearing they suddenly die off from the top, leaving nothing but a bare frondless stem. After examining several trunks of the Big Thatch (*Sabal umbraculifera*) a palm which is so abundant in the district, and finding them completely riddled by the attacks of the larva of a beetle very closely allied, if not identical, with the destructive palm-beetle of the East Indies, I came to the conclusion that one, if not the chief cause of the absence of the coconut palm was the abundance of this beetle. Further information and inquiry in the neighbourhood has fully confirmed this view. The Big Thatch appears to exist and indeed to thrive luxuriantly in spite of the beetle but the coconut fails. The terminal bud of the latter offers an easily accessible and tempting *bonne bouche* to the larva, and it succumbs to its attacks. On the other hand the Big Thatch thrives and covers the country.

It seems as if in this instance a choice must be made between the Big Thatch and the coconut. The work of exterminating the former palm, covering several thousand acres, is an alternative which is neither practicable, nor for some reasons is it indeed advisable. If the ravages of the beetle do not extend to other portions of the Island, it would perhaps be better to accept the inevitable and devote attention in this district to other plants of a more promising and remunerative character.*

Oil of Ben.—A piece of waste land to the eastward of the lighthouse has been cleared and planted with the Moringa or Horse Radish tree (*Moringa pterygosperma*) which is one of the trees yielding the celebrated Oil of Ben. Under the impression that the true Oil of Ben was the produce of *Moringa aptera*, I made inquiry in 1879 respecting this species and asked for supplies of seed from the Royal Gardens, Kew, from Alexandria and Madras. As a result I was informed that Oil of Ben, "though at "one time a valuable branch of Eastern commerce, had "been almost entirely thrown out of the market by excessive imports and extensive adulterations, and but little "of it can at the present time be commercially obtained." Moreover it appeared that what little of the oil that can be obtained is the produce of *Moringa pterygosperma*. This species grows more luxuriantly in all the dry plains of the coast, and it continually bears abundant crops of fruit. With the view of testing its value as a minor product, about 5 acres have been established with it at the Palisadoes Plantation, and in a few years the oil, which is described as the "finest fat oil which a perfumer could use," might be submitted for approval. The seeds are said to yield twenty-five per cent of oil, which at a price say of five guineas a hundredweight—the present market value of sweet almond oil—would surely offer sufficient mercantile inducement for its production; but there is every reason to believe that it would realize never less than ten pounds per cwt. in the open market. For making cold cream and all kinds of unguents it would prove invaluable and without a competitor. Supposing that it would not pay its producers to ship it in its natural state, they could enflower it with the flowers of the plumeria, acacia, jasmin, and pancratium, and numerous other flowers which abound and bloom unregarded: it would then yield six to eight shillings a pound.*

HOPE PLANTATION.

This establishment has received special attention during the year, and it now possesses large nurseries for the propagation and distribution of economic plants, which, in view of the shipping facilities at Kingston, are found of great value.

The chief operations at these gardens consisted in supplying and keeping up the small plantations of Cacao, Liberian Coffee, Nutmegs, Cloves, Cinnamon, Mangosteen, &c. These, when established, are intended to afford seeds and cuttings for the nurseries and for maintaining supplies of these plants in the plains. The Cacao plants, although only 18 months old, are five feet high and exhibit a remarkably healthy appearance. About 600 Mahogany plants have been supplied through the plantation. The Teak plantation of about 10 acres has received two cleanings and is in good order The largest of the Teak plants are 40 feet in height and measuring 2 feet in circumference at the base. The collection of Pine-apples, consisting of the Queen, Prince Albert, Charlotte Rothschild, Montserrat, Ripley, Black Pine, &c., has lately been removed and is now well established in a good position. All the outside fences have been carefully repaired; 80 chains of the penguin fence adjoining the public road has been cleaned and thoroughly established, and a new wire fence placed at Merryman's piece.

Nurseries.—A piece of good land about 2 acres in extent has been enclosed with a hedge of limes and laid out in beds for raising the most important economic plants. The number of these plants ready for distribution amount to 32,000, and among them are Liberian Coffee, Nutmeg, East Indian Mango, Pimento, Oranges, French Limes, Casuarina, Juniper Cedar, Kola Nuts, Teak, Guango, Mahogany, Sapucaya Nut, *Bois immortelle*, Divi-divi, Madras Thorn, Oil Palm, Sappan, Balsam of Peru, Rosewood, Cherimoya, selected Pine-apples, &c., &c.

KING'S HOUSE GARDENS.

General Notes.—In June last an immense number of butterflies of the yellow and white kinds were noticed for several days uniformly flying in an easterly direction. The Grape Vines, last year so much affected by various fungi, have been replanted, fresh soil being added to their roots and all the old entirely removed, with the effect of reducing the virulence of the attacks of these parasitical growths. Stocks of the native vine, *Vitis caribæa*, have also been obtained for the purpose of grafting or inarching on them the European varieties, with a view of obtaining growth free from disease.

THE LACQUER INDUSTRY OF JAPAN.

BY JOHN J. QUIN,

Her Majesty's Acting Consul at Hakodate.

The following particulars are taken from a report intended chiefly as a description of the articles of various kinds illustrative of the lacquer industry of Japan, collected for the use of the Museum of Economic Botany at Kew, under

* According to the Honorable D. Marshalleck, Custos of St. Thomas-in-the-East, slaked lime applied to the crown of the coconut palms has proved of service in destroying the larva of this beetle. This is so simple and convenient a treatment, especially for young trees, that it might well be tried.

* Art of Perfumery, G. W. S. Piesse, Ph. D., F.C.S., p.390.

instructions from Her Majesty's Chargé d'Affaires at Tokio.

Great difficulty has been experienced in obtaining thoroughly reliable information, as not only are the artificers, for the most part, uneducated, but they are entirely ignorant of what takes place in any other department except that to which they have been brought up. A well-known and most intelligent manufacturer, who has been over twenty years himself a worker in gold lacquer, was quite unaware of the mode of tapping and treating the trees, and had never even seen a cut specimen of the wood. He states that his head workman, a highly-skilled artizan, over fifty years of age, hardly knows the name of a single article that he uses.

The *Rhus vernicifera*, the well-known lacquer tree of Japan, is met with all over the main island, and also in smaller quantities in Kiushiu and Shikoku, but it is from Tokio northwards that it principally flourishes, growing freely on mountains as well as in the plains, thus indicating that a moderate climate suits the tree better than a very warm one. Since early days the cultivation of the tree has been encouraged by the Government, and as the lacquer industry increased, plantations were made in every province and district. The lacquer tree can be propagated by seed sown at the end of January or the beginning of February. The first year the seedlings reach a height of from 10 inches to 1 foot. The following spring the young trees are transplanted about 6 feet apart, and in ten years an average tree should be 10 feet high, the diameter of its trunk 2½ to 3 inches, and its yield of lacquer sufficient to fill a 3-ounce bottle.

A more speedy method is, however, generally adopted. The roots of a vigorous young tree are taken, and pieces 6 inches long and the thickness of a finger are planted out in a slanting direction a few inches apart, 1 inch being left exposed above the ground. This takes place in the end of February and through March, according to the climate of the locality. These cuttings throw a strong shoot of from 18 to 20 inches the first year, and are likewise planted out the following spring. Under equally favourable circumstances these trees would in ten years be nearly 25 per cent larger in girth, some 2 or 3 feet higher, and would yield nearly half as much more sap than the trees raised from seed.

It has not hitherto been the custom to bestow any special care on the trees after planting them out, but in cases where leaf or other manure has been applied they are much finer. Of late years hill sides and waste grounds alone have been used for lacquer plantations, as, owing to the rise in the price of cereals and farm produce generally, it does not pay the farmers to have their land cumbered with trees. Those that have been hitherto planted along the borders of the fields are being rapidly used and uprooted, and, where practicable, mulberry trees are planted instead, with a view to rearing silkworms. Nevertheless, as a good workman is expected during the season to tap an average of 1,000 trees ten years old, and as the Province of Yechizen alone sends out about 1,500 "tappers" yearly to the various lacquer districts, it will be seen that an immense production annually takes place, stimulated, doubtless, by the demand for cheap lacquered articles abroad. To remedy the possible exhaustion of the supply, and in view of the great rise which has taken place in the price of lacquer, several companies are being projected to plant waste lands with the trees. A ten-year-old tree, which some five years ago only cost from 1 to 2 sen, now costs 10 sen, which, allowing even for the depreciation in the value of the paper currency, shows a rise of about 500 per cent.

The best transparent lacquer comes from the districts of Tsugaru, Nambu, Akita, and Aidzu. It is largely used by the workers of Kioto, Osaka, and the southern provinces, but though also used in Tokia is not so much appreciated there as the lacquer produced from the neighbourhood of Chichibu in the Province of Mus-ashi, from Nikko in Shimotsuke, and that produced in the Provinces of Kodzuke and Sagami, which hardens more rapidly, and is best for black lacquer.

There are some districts the lacquer obtained from which is best for certain kinds of work, but is not so well adapted for others. The kind which is used for transparent lacquer is mixed in large tubs, to insure a uniform quality, and being allowed to stand for some time (say, a week or ten days), the best portion, which is ordinarily 70 per cent of the whole, is skimmed off. This is used for *Nashiji* and *Shu* lacquer, while the remainder is used for making inferior mixtures, such as *Johana*, etc., all described elsewhere. Almost all the various classes of lacquer are similarly dealt with to insure uniformity, as some qualities dry much quicker and are better than others, and the slow drying qualities would otherwise remain unsold.

The whole country produces at present on an average from 30,000 to 35,000 tubs per annum, each tub being of about 4 gallons capacity. Some 70 to 80 per cent of this total amount is produced from Tokio northwards. Nearly one-half of the lacquer produced is sent to the Osaka market, where it is prepared as required and resold all over the western and southern provinces, the remaining portion being used up locally and in Tokio.

The usual age at which a tree is tapped is ten years, but in some few cases a tree is tapped when only three or four years old. The best lacquer for transparent varnish is obtained from trees from one to two hundred years old, as their sap has more body, and is more glutinous. The tools used in obtaining the lacquer are as follows:—

Kawa-muki (bark parer), a curved knife with which the workman smooths all inequalities of the bark before tapping the tree.

Eda-gama (branch sickle), an instrument with a gouge on one side and a knife on the other, fitted with a piece of bamboo to give the hand a good hold when tapping branches.

Kaki-gama (scraping sickle), a similar instrument, without the piece of bamboo used for tapping trees generally.

Yeguri (a gouge), used in autumn to scrape the bark smooth before giving the final cut with the *kaki-gama*.

Natsu-bera (summer spatula), used for scraping the sap out of the incisions into the receptacle named *go*.

Hocho (knife), used for cutting the bark of branches in obtaining *seshime* or branch lacquer.

Seshime-bera (seshime spatula), used for collecting the sap which exudes from the incisions in the bark of the branches.

Go, the bamboo or wooden pot, in which the sap is put as it is collected.

Go-guri (pot gouge), a long straight knife for scraping the lacquer out of the pot into the tub.

Te-bukuro (glove), worn by the tapper to protect his hand from contact with the sap.

The first tapping takes place about the beginning of June. The standard number of trees allotted to a tapper for the season is 1,000—presuming them to be about ten years old (the size of the small specimen), about 800 of the size of the large specimen, and so on, less and less according to the size of the trees. Having cleared away the grass from the roots, the workman makes the round of his allotted trees, marking each with small notches about ½ inch long. The first of these notches is made about 6 inches from the bottom of the tree on the right hand side; and next, one "hand stretch" higher up on the left hand side; the next, one "hand stretch" higher on the right, and so on, alternately as far as the workman can reach. These preliminary markings, which are to determine all the places for subsequent tapping, take fully four days, being at the rate of 250 trees a-day. The tapper then goes round, provided with the bark scraper, the ordinary scraping sickle, the summer spatula, and the pot to hold the lacquer, and first smoothing the bark where required gives one cut above and one cut below the two lower marks, and one cut above the remainder of the other marks, the cut being in each case about 1½ inch long. After giving the cut the instrument is reversed, and the knife is run along the incision to insure the bark being entirely cut through. This process is repeated every four days, each incision being made a little longer than the preceding one, up to the fifth tapping, inclusive, after which the remaining incisions are made of the same length. At each round, when all the requisite incisions have been made on the tree, the workman gathers the sap which has exuded with the spatula, beginning with the two lowest incisions, and so on to the uppermost cut. Twenty-five is considered the normal number of cuts, which, at the rate of one incision at each place every four days, occupy one hundred working days, and allowing for some twenty days of rain

during which the sap cannot be drawn, the season is brought to a close by the end of September. If the workman has any large trees to tap, the whole of which he cannot reach when making his ordinary rounds, he taps all he can reach, and when his round is concluded he returns with a ladder, and mounting each tree taps the remainder of the trunk and the leading limbs in the same manner as above described, previous to making a fresh round.

When the full number of incisions has been given, the workman gives an extra long cut underneath all the initial notches on each tree to obtain the sap which has collected there, and another above the uppermost cut of each set. These incisions are called *Ura-me* (back marks). The workman also makes a number of cuts, each about a foot apart, in all the branches whose diameter exceeds 1 inch. This operation requires about sixteen days to get through the whole number of trees. The next operation is called the *Tome* (the finish). This consists in a number of incisions completely encircling the tree wherever the workman perceives a likely place. The next process consists in cutting off all the branches: the larger ones are once more tapped after being cut off to extract any sap that may still remain in them, and the small branches which have not yet been tapped are tied in bundles and steeped in water for about ten days. When taken out and dried the bark is cut with a knife, and the sap which exudes is collected with the branch spatula, and is called *Seshime* lacquer. This wood seems to be derived from *Sehi*, the name of a machine, and *shimeru* (to press), from a practice which obtained in olden days of pressing the branches in such a machine to obtain the sap. It is also known as *Eda urushi*, or branch lacquer, which latter more explicit term is, for the sake of convenience, used throughout this report.

The sap obtained from the first five cuts above each notch is poor, containing, as it does, a large proportion of water; the middle fifteen cuts produce the best sap, and the sap obtained from the last five incisions is poor, and lacks consistency. Again, the sap obtained from the *Ura-me* (back marks) and *Tome* (finishing) cuts is very good, and dries quickly.

The sap from the first twenty-five cuts is mixed and sold together, but the *Ura-me* and *Tome* sap is almost always mixed and sold separately. The operations above described kill the tree in one season, but frequently the tree is made to last two years or more, by giving only half the number of incisions, and reserving the *Ura-me* and *Tome* cuts for the final year. The sap obtained the second and following years is, however, of an inferior quality, and this method is only resorted to by private individuals, who tap their own trees during the intervals of farming. Ordinarily, a wholesale dealer in lacquer buys so many thousand trees from the owner, and, as a matter of course, extracts the sap with as little delay as possible, making a contract for the purpose with professional tappers. A first-rate workman will receive over 100 yen (equal, at the present low rate of exchange, to nearly £13 sterling) for the season, and can collect four and-a-half tubs (equivalent to 18 gallons), but the average receive 75 yen, and collect proportionately less. The present price per tub of lacquer ranges from 90 to 100 yen.

After the sap has been taken the exhausted tree, which remains the property of the seller, is cut down by him, and is used for firewood, for building purposes, or for making boxes. The roots of the young trees throw from three to five shoots the following spring, and these can be used in six or seven years. Of these five sprouts three are commonly much stronger than the other two. In such cases, the strong ones only are tapped and cut down, the weaker ones being allowed a year or two longer to grow, when, receiving the whole of the nutriment, they shoot up in one year as much as an ordinary tree would in three. After tapping and cutting down, fresh shoots to the number of five are again allowed to sprout, and so on, the root not seeming to become exhausted by the process; but when a very old tree is cut down the root will not give out new shoots. In the northern provinces very old and large trees are met with in considerable quantities. These were kept for the sake of their berries, from which the wax used for the Japanese candles was obtained. This was the more profitable use to which to put the tree, as a good tree, from eighty to one hundred years old, yielded yearly, on an average, equal to 6*s*., while the price of a ten-year-old tree to be used for extracting the sap was under ½*d*. Previous to the revolution of 1868 every tree reserved for making wax was officially registered, and the owner was not allowed to mutilate it in any way. Even if a tree died, he had to get official permission before removing the stump. The Shogun's Government and also the local magnates had large plantations of the lacquer tree reserved for wax, but since the opening of the country to foreign trade, and the introduction from abroad of kerosine oil, the wax industry has greatly declined, and there are now no restrictions on the free sale of the tree for tapping, and, consequently, all the fine old trees (which will sell for from 5 to 6 yen each) are fast disappearing.

To show the relative value of the berries and the trees a few years ago, the following may be cited:—A wholesale lacquer merchant informed me that five or six years ago he went as usual to purchase trees in the district of Aidzu, and among others bought one tree for a yen (then equal to 4*s*), the owner reserving the berries that might be got as his own property. He does not consider the bargain was a cheap one, but the owner realized the sum of 80 sen (equal to 3*s*. 2*d*.) from that year's yield of the berries alone before cutting down the tree.

It should be mentioned that the above description of the method pursued in tapping the lacquer tree is that which is recognized as the proper one; but, as even the specimens of the lacquer tree forwarded will show, the rule is not rigidly observed, the style and size of the tree, and the caprice of the workman, combining to cause variations in the number of incisions given in each series.

Various Woods used in making Lacquer Ware.

The woods chosen for lacquering on are naturally selected according to the use to which the lacquered article is to be put. For shelves, cabinets, and boxes of all kinds, the following are principally used, and are set down in the order of their excellence:—

Hinoki (*Chamæcyparis obtusa*).—This is by far the best wood for making boxes, as it does not warp.

Kiri (*Paulownia imperialis*).—A light wood, used for clothes boxes, which are only lacquered on the outside. It is also used for making teacaddies, as the wood has no smell.

Hono-ki (*Magnolia hypolema*).—All sword sheaths have hitherto been made of this wood.

Sawara (*Chamæcyparis pisifera*).—This is a wood of a coarser grain than *Hinoki* (*Ch. obtusa*).

Hime-ko-matsu.—This wood is used for carved figures of men, animals, ect. It is not liable to split and crack.

Tsuga (*Abies tsuga*).

Hiba (*Thujopsis dolabrata*).—Used for making cheap articles.

Akamatsu (*Pinus densiflora*).

Sugi (*Cryptomeria japonica*).—This wood is only used in making the cheapest and most inferior goods.

The following woods are mostly used in the manufacture of such articles as are turned in a lathe, as bowls, rice cups, round trays, etc:—

Keyaki (*Planera japonica*), the best being obtained from the province of Hiuga.

Shoji.

Sakura (*Prunus pseudo-Cerasus*).

Katsura (*Cercidiphyllum japonicum*).

Tcho (*Ginko biloba*).

I-go.—Grown in large quantities in the neighbourhood of Hakone. It is principally used in the manufacture of toys and cheap articles.

Buna.—Principally used in the district of Aidzu for the same kind of utensils as *Keyaki* and *Sakura*, but being a brittle wood, it cannot be turned in a lathe to make such fine articles; those made of this wood are coarser and heavier. For raising gold lacquering over the unvarnished surface, the following hard ornamental woods are often used:—

Shitan.

Tagayasan.

Karin (quince).

Kuwa (mulberry).

Keyaki (*Planera japonica*).—Ornamental grain.

MR. STORCK ON THE TREATMENT OF THE COFFEE LEAF FUNGUS.

We call attention to the letter with which Mr. Storck of Fiji has again favoured us and in which he now recommends the Ceylon planters to try—not 10 or 25 per cent of carbolic acid, in water—but 100 per cent or the unmixed raw acid, in fighting the coffee leaf fungus. Mr. Storck gives this advice with the same confidence of success that he had in recommending, first, a ten per cent and afterwards a twenty-five per cent solution; only he does not say this time that he has already demonstrated the absolute and final efficacy of his process. Far from it, Mr. Storck now incidentally mentions the persistency of "the yellow spots" in shewing themselves many months after it was supposed the remedy had eradicated the disease. In other words the sporangia so protect the spores that it is more difficult to kill them than Mr. Storck at first supposed. Indeed we cannot help thinking that our friend in Fiji is only going through the slow and painful process which has already been experienced by so many in Ceylon, more especially since 1878-9, of finding out that any merely local or temporary success in fighting *hemileia* is no guarantee of a sufficient remedy being discovered to apply to a whole country, or even a coffee district, or let us say a whole plantation of 200 to 250 acres. We would therefore advise Mr. Storck not to incur the expense of a journey to Ceylon until he has gained some more experience of the effect of his treatment in Fiji. For, let us tell him that several weeks ago we heard of local experiments with carbolic acid, pure and simple, in the case of Liberian coffee by a very careful experienced planter who had previously tried solutions as recommended by Mr. Storck up to 25 per cent without a satisfactory result. We think we heard that the "raw acid" was also found wanting: at any rate no news has come of such a success as would warrant more extended and expensive trials. While there is a splendid field in Ceylon for the utilization of a cheap and really effectual remedy for coffee leaf-disease, let us warn Mr. Storck that there is little or no scope now—capital being so scarce and every rupee on outlay having to be carefully considered—for mere experimentalizing on any but the most limited scale. When Mr. Storck is able to furnish the Ceylon planters with a certificate signed by one (like Mr. Arthur Stephens or Mr. Whitten) who knows what leaf disease in Ceylon means, that he has so succeeded in keeping some hundreds of acres—previously affected by *hemileia vastatrix*—entirely free of any attack for at least one year:—then we may venture to recommend him to come over and supervise the application of his remedy. But at present if his confidence is entirely based on the effect of the vapour arising from pure cabolic acid, we fear it will yet be disappointed so far as the death and permanent eradication of the spores are concerned.

MR. STORCK ON HIS TREATMENT OF THE COFFEE-LEAF FUNGUS: PURE CARBOLIC ACID NOW RECOMMENDED FOR THE VAPORIZATION PROCESS.

Belmont, Rewa river, Fiji Island, 14th Sept. 1882.

DEAR SIR,—When I wrote to you last to give you and your readers an account of a twelve-month's experience of the treatment of *hemileia vastatrix* by carbolic acid vapours, as practised and recommended by me, I advised the use of a fluid mixture containing 25 per cent of acid in water as sufficient for infallibly and thoroughly destroying that pest. I must, however, plead guilty to having kept back what at the time I thought a rather too sudden departure from the directions given in earlier papers, and what I feared might surprize and alarm, especially those of your readers who had already started or made preparations for an earnest trial of my method: but the following I hope will be accepted as an intelligible and sufficient explanation for any further alterations projected by me.

Any one using the above specified proportion of acid will find that the sheet of water covering the acid grows thinner with every application and that after some 4 or 5 fortnightly supplies, there is no more space left for any water, simply because the periods of supply are disproportionate to the consumption of acid, which means, in other words, that the vessels will be full of raw acid in direct contact with the atmosphere, instead of still containing a body of water which had in a way served as a screen between it and the acid, rather than as a medium of solution, and only permitting a certain restricted amount of vaporisation.

What I had not the boldness to recommend in my last paper I do now and say: "*use raw acid and use it fearlessly, as it hurts nothing*"! Half a pint of raw acid will in a vessel of four inches diameter work and last 3 months and longer, causing an expenditure of about 4 gallons per acre a year. During my observations of the 25 per cent charge, I had for some time been thinking of reversing the proportion of the mixture as originally recommended for weekly supplies, thus containing a thin sheet of water above the acid, by way of tempering the vapors arising; but, as this would have meant a resumption of the troublesome weekly system, and defeated my object of farther economizing labour, I came to the conclusion that the boldest course is the best. and have now made a clean breast of it. The alteration, in short. consists in this: that, instead of restricting generation of vapour by means of water, I now trust to dilution of the carbolic fumes through the atmosphere, my best ally. I was the more encouraged in introducing this change, that one of the chief features of my permanent automatic system is the economy of labour, as in many cases, for instance, in that of this colony, it would be far easier for a man to buy chemicals, a mercantile commodity, a chattle, than labour, the supply of which is often dependent on many contingencies, artificial or natural.

For some time past I have been thinking of an improvement in the vessel as first described by me, and have resolved on the following:—"Dimensions remaining the same, the saucer receives a vertical rim ¾ inch high pierced by twelve ½ inch holes; the roof, which is *close* at the top, also receives a vertical rim, leaving a slight projection for carrying off drip, and pierced in such a manner that the holes in it correspond with those in the rim of the saucer. With an easy fit of the top part of the vessel *over* the rim of the saucer, a slight turn with the hand will shut off an unnecessarily large access of air, consequently diminishing the generation of vapour in the same ratio, even to completely stopping it, and as a matter of course also the consumption of material, if desired. The vessel thus combines compactness with every requisite for economy and perfect control, nor need the price of it much exceed that of the original.

But before your planters go to the expense of the special vessel, they may start a trial treatment with anything they can procure in the way of jam tins, preserve cans, wide-mouthed bottles, etc., whilst zinc or tin casehining, slate, shingles and similar things may serve for roofing. Put the vessels on the ground with

3 4 pegs round them and either *bend* the roof over and down between the side of the vessel and the pegs, or put a couple of sticks across the mouth of the vessel, lay your roof on flat with a slight slope to windward and a stone on the top of it to keep it down, but always remember that the larger the area the better. If a ½ pint charge seems too much to risk for a start, ¼ will do, but pure. Never attempt to play with *Hemileia vastatrix*, as I was in a manner compelled to do in the way of experiments, because, as sure as you do so, you will produce a crop of those obstinate, barren-looking, smooth, yellow spots, which although not fatal to the leaf, will break out and produce fresh spores always weak and often dead, but nevertheless suspicious, at the first relaxation in the treatment. I have seen them do so after nine months of apparent inertia, just as if they at first only scotched, in reviving, become inured against the action of the enemy, every month more difficult to kill until they finally drop with the leaf.

The grave difficulty apprehended by one of your correspondents in trusting coolies with the acid is effectively met by a suitable vessel, something like a large kerosine lamp feeder, close all round with a small nozzle carrying some 2 gallons. A watering-pot will do. There are some with shut-down lids. I never contemplated carrying the chemical about in open soup-tureens or on dinner-plates and to ladle it out with table spoons. As for the folly of attempting to envelope a coffee field in the fumes of carbolic acid, let him live and learn.

Do not wait for me, but let your planters go to work and make themselves familiar with my treatment and its effects; all is so simple that it precludes the possibility of any mistakes. There are now preparations being made here by the manager of the Mango Island Company for an extensive trial of my cure on a plantation of about 160 acres of grown coffee, and on one or two more estates, which movements will claim my most immediate attention for a while, but I will be with you as soon as I can get away—at any rate at the end of this season's planting.

On page 548 of the *Weekly Observer* of June 30th, there occurs in connection with Mr. Parr's report upon the treatment his estate received at the hands of the Fijian Government a footnote to the effect "that all this must have happened before Mr. Storck had thought of carbolic acid fumes as a remedy against *hemeleia vastatrix*." Precisely so, Mr. Editor, but you will recollect that I had not had the advantage of a ten-years' acquaintance with the fungus, enjoyed by the gentlemen of another crown colony I know of. The fungus had then only been a few months in the country, but I took a deep interest in it from the first, and was enabled, after some personal observation and through reading up the then available literature on the subject, to offer Government a manual treatment of the leafless coffee tree, which I flattered myself then, and am sure of now, would have done the work under the conditions given, isolation of Mr. Parr's estate, with the aid of an Ordinance capable of compelling simultaneous action throughout the country, and the then insignificant proportions of the coffee industry of this country. The fate of my propositions to Government cannot be a matter of discussion in the paper before you, as being foreign to and beyond the main subject.—I am, dear sir, yours faithfully, JACOB P. STORCK.

STATISTICS OF CINCHONA BARK.

There is no more certain fact than that millions annually of the human race, and we might add of domestic animals, also, perish for want of ample supplies of the medicine, composed of the alkaloids of cinchona bark, which is almost a specific in case of malarious fevers. One of the most hopeful signs of our times, therefore, is the enormous increase which has recently taken place in the production of bark and its manufacture into quinine or the allied alkaloids. Much of the increase is, no doubt, due to the export from South America mainly of cuprea bark, the bark of a tree botanically distinct from the cinchona, but possessing the same tonic and febrifuge properties. That the average prices of cinchona bark should have remained so steady in the face of the market flooded by this inferior substitute shews how largely the consumption of the alkaloids must be increasing. This fact is strikingly exhibited in a pamphlet issued by Mr. John Hamilton, lately of Dikoya, Ceylon, whose valuable contributions to our columns cinchona planters have appreciated. A mistake in some statistics furnished to us by Mr. Hamilton some time ago, it is now explained, was due to a printer's error in the monthly accounts of the Board of Trade, which, it seems, give in any case only approximations, the correct figures being found in the annual accounts. The figures now furnished to Mr. Hamilton shew a perfectly astounding increase in the imports of bark to Britain, with considerable advances in many other countries. In looking at values, Mr. Hamilton reminds us that we must take into account an average greatly lowered by the inpouring of cuprea bark. He might have added the effect of the large quantities of twig bark sent, especially from Ceylon. The increase in imports into Great Britain was from 2,535,000 valued at £218,000, in 1870, to no less than 14 040,000 lb., valued at £1,814,000 in 1881; an increase of 11,504,000 lb. and £1,595,000 in 12 years! While the imports from the United States of Colombia had increased eight-fold, the adverse influence of war in the case of Chili is shewn in a decrease equal to twelve-fold. The increase of imports into Britain was gradual until 1880, when a leap was made from 9 millions of lb. in that year to 14 in 1881. Ceylon told for some of this increase in 1881, but the influence of our island will be much more apparent in the figures for 1882. The importations from British India are given from 1876, and they evidently include bark from Ceylon, as our London correspondent points out. We are rather surprized that Mr. Hamilton did not discriminate the bark from Ceylon. With the proviso that not quite all the bark exported from Ceylon goes to Britain, we now give the figures for total imports from the British East Indies with those for exports from Ceylon:—

	Imports from B. I.	*Exports from Ceylon.*
1876...	154,480 lb.	56,589 lb.
1877...	511,168 ,,	173,497 ,,
1878...	514,864 ,,	373,511 ,,
1879...	1,004,080 ,,	1,208,518 ,,
1880...	1,814,736 ,,	1,207,720 ,,
1881...	1,864,912 ,,	3,099,895 ,,

There are discrepancies here which we cannot reconcile, especially in the case of 1881, when only an aggregate of 1,864,912 was imported into Britain from the East Indies against over 3 millions of lb. exported from Ceylon alone. Can the balance have gone to the continent of Europe? The difference between calendar years and seasons could not produce the discrepancy? Britain seems to have imported from France and other western countries as well as exported to them, but as a general rule, keeping the best barks to manufacture into quinine. Of the 14 millions of lb. imported into Britain in 1881, more than half (nearly 8 millions, in truth,) came from the United States of Colombia, but a large proportion of this was cuprea bark. The East Indies rank second as a source of supply; with Peru third; France fourth (but Britain exported thither about as

much as she imported); and Ecuador sixth. The vaerage prices in Britain have ranged from 1s 8½din 1870, the lowest, to 2s 11¼d, the highest in 1879 With the enormous imports of 9 and 14 millions in the two succeeding years, the figures went down only to 2s 7¾d and 2s 7d, while the mean average for the twelve years was 2s 2¼d. These figures are surely encouraging, even when we find that out of the 14 millions of lb. imported in 1881, one-half wsa exported. The actual consumption of bark in Britain has risen from 1,104,000 lb. in 1870, to seven millions last year The United States of North America seem to receive the vast bulk ofthei' supplies of bark from the United States of Colombia—cuprea mainly—although no fewer than 28 sources of supply are enumerated. As our readers are aware, the duty on quinine imported into America was recently abolished, much to the anger of the manufacturers, who thought *their* industry as much entitled to protection as others. There can be little doubt that, from the date of the abolition of the duty, the larger quantities of quinine imported would react on the figures for bark and so we find that the quantity of the latter, which rose from 1,976,000 lb. in 1877 to 6,388,000 in 1879, went down to 4,2 01,000 in 1881. The prices in the five years ranged from 1s 1¼d to 1s 9d, the mean average being 1s 3⅜d. It is significant that imports from Colombia went down from 5,248,000 lb. in 1870 to 1,738,000 in 1881 ; the imports from England rising from 617,000 lb. in 1879 to 1,242,000 in 1881. In this case we should like to see the quantity of quinine imported from England and France. The imports of bark into the latter country rose from 2,079,000 lb. in 1877 to 7,950,000 in 1881, England contributing 3,046,000. But the chief source of increase was in the rise of Colombian bark from 1,430,000 in 1880 to 3,392,000 in 1881, most of the increase being doubtless in cuprea. Of the 7,950,000 lb. imported, only 3,017,000 were consumed, so that France, for decoctions and alkaloids, uses bark only equal to 3·7ths the quantity employed in Britain. Of the imports of bark into France the larger portion is *en route* to countries in the interior of Europe. The consumption in France rose in 1881 so as to be higher by 2½ millions of lb. than in 1877, and the average value was enhanced from 2s 4½d per lb. to 2s 10⅞d, the mean average for the 5 years being 2s 8¼d. In Germany the bark imported and used had risen from 1,430,000 in 1877 to 4,769,000 in 1881, the value rising from 2s in 1877 to 4s 1d in 1880, and 3s 2d in 1881, the mean average for the 5 years being 2s 8½d, exactly as in France. The importations of bark into Italy rose from 990,000 lb. in 1876 to 1,807,000 in 1880 and then at a bound, to 5,546,000 in 1881. There is an important factory in Milan, and about 4,000,000 lb. of bark was converted into quinine in 1881, besides the quantity used in the rough state by the inhabitants of marshy and feverish places. American bark is said not to be imported direct into the Netherlands, but such bark must enter largely into the imports from England, which rose from 1,113,000 lb. in 1877 to 2,910,000 in 1881. The bulk received at Amsterdam from Java rose from 4,027 lb. in 1879 to 178,000 in 1880, the estimate for 1881 being 220,000. This was Government bark. From private plantations the imports are now larger than we expected—having risen as follows :—

1879 50,000 lb.
1880 160,000 ,,
1881 90,000 ,,

The average value of Government bark ranged from 1s 11½d in 1870 to 3s 4d in 1877 ; 3s 3¾d in 1880 and down again to 2s in 1881, the mean average being 2s 4d per lb. This is lower than we expected and knowing that some of the best Ledgeriana bark sold for over £1 sterling per lb., we are surprized at the low averages for Ledgeriana alone, even although much of it may have been twig bark. The average for 8,807 lb. in 1878, yielding from 5 per cent min. to 8 per cent max. quinine, was only 1s 9d; while the highest price 6s 8d was realized by 4,317 in 1876, yielding only 3·09 to 7·02. In 1881 the quantity was 4,180 lb. yielding such high results as 5 to 9 per cent of quinine, but the value realized is not stated. These are some of the interesting facts in Mr. Hamilton's book, and as he tells us he is to send 200 copies to Ceylon for sale, cinchona planters and all interested in the enterprize will have the opportunity of seeing the full details.

THE EKMAN FIBRE PROCESS.

Mr. Thomas Christy, of Fenchurch Street, London writes to us:—

"I informed you by last mail that Routledge was working up the question of the Ekman process, and he is now so satisfied that nothing can touch it, that he is asking for special terms as to royalties. I think this is a pretty good proof of the value of the Ekman patent, and that it can be relied upon to do the work that it is said to do.

"The reason Routledge wants some concessions is that he has made certain promises which he is unable to perform, and, if he adopts the Ekman process, naturally the people will not pay him a profit over the usual royaltics, but I think the matter has not gone so far in India, but what the royalties can be augmented all round for the public so as to squeeze in the small preferential royalty for him. He has worked so indefatigably to try and find a proeess, that I think the fact of his accepting the first rule of working the invention with such alacrity speaks highly for this man's character.

"I must tell you, to gnide any remarks you may make, that I think it will be quite likely that he may not feel that he can push bamboo in presence of many fibre-yielding products that exist in the East. Take for instance hemp. This when ripe gives 40 per cent of fibre-making material, but the farmer can get his crop of seed from the same stems, so that in reality, after he has got the crop of seed instead of throwing away the hemp stems, he can allow them to finally dry and then boil them in the cylinders, or sell them to the owners of the cylinder."

We regret to learn that Mr. Routledge has given up the idea of utilizing bamboo stems. Bamboos grow wild in jungles, while hemp has to be cultivated and is a most exhausting crop. We long ago saw that Mr. Routledge's idea of converting the tender shoots of bamboo into "half stuff" for paper would fail, because to remove the young shoots would mean the extirpation of the plants. But if the stems could be treated chemically and converted into fibre, large supplies could be cheaply obtained of the various species from the gigantic bamboo of Burmah to the *batala* of Ceylon.

NEW PRODUCTS IN THE LOW-COUNTRY OF CEYLON :

GENERAL PLANTING REPORT : SEPTEMBER AND OCTOBER.

WEATHER.—There was hardly one day in the two months without more or less rain; we have recorded dry weather for a fortnight in September, not because there was no rain, but because the rain fell in the night, and did not interfere with work. Throughout October the wind has been variable, and not much of it, but the rain has been all from south and west, lots of it day and night, and for hours together. On the last three days of the month there was none, but it opened afresh with November.

HEMILEIA.—The spreading of the fatal fungus, during these two months has been heart-breaking; I need not attempt description, every one who has seen a Liberian coffee field badly touched with hemileia (and alas they are not few) knows what it is. Two months ago, I had as fine a lot of nursery plants as heart could desire, today I have hardly one out of 20,000 unaffected.

THE MOLE CRICKET.—I thought I had during past years become well acquainted with the seasons and habits of this pest. In past years, they appeared in March and September and continued to operate for ten weeks, on each occasion, while the remaining months were entirely free from them. This year they did not come in March, but began the campaign in July, just as I had planted out 6,000, and now at the end of four months they have not ceased to cut plants, some with stems as thick as a goose quill. On some spots they have made a clean sweep and altogether I have lost more than two-thirds of the plants put out, on one side of the property, while on the other, I have not lost above seven or eight per cent. It is not only coffee plants that have suffered this season, ninety per cent of the cocoa plants put out in July were destroyed, and of large strong plants put out in October, a large percentage have been cut already; out of 300 Peruvian cotton plants, I have lost nearly one-half, and getting up a kitchen garden is utterly out of the question.

COCOA.—About a score of the oldest, and best sheltered trees are bearing, from one to fifty pods, and some hundreds are promising to do something in the course of next year, and since the winds have been moderate, the plants are pushing out fresh leaf, and when they once get into form, they get on rapidly though on some exposures, and on some soils, their cultivation seems hopeless, I am laying down fresh nurseries as the pods come ripe. I have heard it suggested that the youth of the trees may be a drawback in respect to the vigour of progeny, but I can see no good reason why it should be so. If I find a good large pod full of plump firm nibs, I cannot see any reason for rejecting it, because it is the first fruit of its parent tree.

I have down a NUTMEG nursery of 800 seeds that are just beginning to come up, and a large proportion of them seem to have germinated. I am preparing land for them by leaving a good deal of shade; if by and bye it should be found they do not want it, it can be removed. The survivors of a few plants I put out on another place, three and a half years ago, have been flowering for the last three months, but only male flowers have yet appeared.

The WAX PALM is a very slow coach, six months, and only one leaf like a large blade of grass. What the plants may be doing underground I do not know, but above ground they are precisely where they were two months ago, a few germinated seeds of this plant that were sent to me, all perished, though the greatest care was bestowed on them.

Since I sowed (upwards of twelve months ago) there has been no six days without rain and the CARDAMOM plants have continued to perish, they died in the seed beds under a roof, they died in the sheltered beds outside to which they were transplanted, and they have continued to die when put out, under moderate shade. Five per cent. of the lot survive, and the strongest have thrown out a multitude of shoots from the root, all taking an angle of forty-five, and all rotting off before they get a foot above the ground. I chose a piece of ground on which the jungle ginger (a kindred plant) grew naturally. I do not like any plant I take in hand to baffle me and I will still fight with it, though the battle is not always to the brave.

The different species of the CITRUS family do well here, if they can be got up to a height of eighteen inches, but it is extremely difficult, to rear them out of danger; what with the variety of poochies, that prey on them, I think myself lucky if I rear one in twenty of the seedlings. The Rambutan thrives well, and seems hitherto insect-proof. I have got some fifty of them about the field, getting on much better than I expected.

Six months ago I mentioned, that I was inclined to try if the Pepper Vine would cling to the bare rock. I had never seen it do so myself, but some of my Singhalese neighbours assured me it did. I put myself into their hands, they brought six coolie loads of vines, cut them into one foot lengths, and planted them in handfulls at the base of the boulders. I demurred to the quality of the cuttings, as being mostly too old, and to their mode of treating them, but they assured me they knew what they were about, and I left them to their own devices; for months not a bud appeared, and I gave it up as a failure, but lately a few of them have taken a start, and are getting on. They show some reluctance to attach themselves to the rock, and seem rather inclined to trail along its base. I am, however, coaxing them to climb, and hope to succeed, in clothing the multitude of bare boulders with profitable foliage. It is a curious fact, that on some of the cuttings that have never opened a bud, there are strings of fruit, that seem likely to ripen.

VANILLA seems to take well with our soil and climate, the cuttings put down in April, are (some of them) three feet high, and I think that cultivation is likely to succeed, if it be found worth while to extend it.

Nothing grows like the Ceara rubber; in twelve months it is twenty feet high, and shades with its branches a circle of equal diameter; were it not that the seed is the most intractable in the vegetable kingdom, it would soon be a weed, as common as lantana itself. The grand question still to be solved, is, whether the produce will pay for collection. I suspect it wants a drier climate than South-west Ceylon to render its sap rich enough, to discharge the cost of labour connected with it.

ASSAM HYBRID AND CHINA TEAS IN CEYLON.

In response to the "Assam Planter" whose letter appears below, we may say that there is some good China tea on Abbotsford from seed which came from Darjiling, and which we declined to uproot when advised to do so. But the vast majority of the plants are first class hybrid, mainly from seed from the Assam Company and nothing can be more satisfactory than the growth and yield, which an Assam planter who recently visited the estate will testify. Our correspondent must remember that an average of 5,000 feet within 7° of the Equator, is a very different thing to 27° away from it. An altitude of 5,000 feet in Ceylon is about the equivalent of a little over 3,000 in Darjiling, with reference to *mean* temperature.

TEA: ITS PRESENT AND FUTURE IN CEYLON.

SIR,—A correspondent, recently quoting from Col. Money's 3rd edition of "Tea Manufacture and Culture," speaks against the planting of tea at high elevations. I have not myself had the pleasure of reading any one of Col. Money's essays, but from all I hear they are well worth perusing; yet at the same time I do not hold with that gentleman. His remarks, that tea will not do at high elevations, are disproved by the cases of Darjeeling, Nynee Tâl, Almora, Dhera Dhoon, etc. These are places where tea has been long cultivated, and, if the yield of these places were put before the public, acre per acre, it will be

found that the yield is not far short of lower districts, and the lower cost of manufacture in many instances counterbalances any short flushes. The aroma in manufactured teas at high elevations is far superior in almost all cases.

I most certainly think, in a good many places at high elevations in Ceylon, tea of a wrong kind has been planted at an elevation of 5,000 to 6,000 feet and upwards. A fair hybrid China is what will most undoubtedly thrive and well too. Most estates are going in heavily for the Assam variety and at high elevations : this is a fallacy and one that will by experience and practice prove a mistake. A good class of China (of which there are a large variety) put out at any thing over 5 000 feet and pruned heavily at the proper time, will give a very fair amount of flushes, and where care is taken in the picking a much finer tea than Assam hybrid will do ; the percentage of orange tips and Pekoe larger.

A correspondent of the local *Times* of the 29th ("R. M.") speaks of the blunders early committed by a good many men at Ceylon and mentions as an instance, "the man of Abbotsford."* What, may I ask, are the class of plants put out on that estate and what the elevation? Or even take "Oliphant estate?" If I remember rightly, Assam hybrid was tried on both these estates. If I am correct, would not a *China* variety have done better? (I simply ask the question and do not for a moment say that these estates are not doing well). In advocating for Ceylon as a tea district, I speak with confidence, and there is not a shadow of a doubt that it will be one of the leading districts in the East. "Unity is power" and what is wanted to make it so is that, in every instance where good has succeeded, it should be made known through the medium of one of the local papers. The parent Association should call for essays on tea, and let it be essays open to every one, a member or not. What can be better than the results already derived from tea cultivation in Ceylon? The yields in almost all instances have been good ; the teas, taking inexperience and disadvantages, very fair indeed, and the report from tasters at home very creditable. A large number of planters have at first had failures in nurseries which was expected, but since the last few years better prospects have turned up, and tea is being extended in almost every district. The future, I say, for Ceylon, is still before it, and tea will take a widespread name with care and proper treatment

AN ASSAM TEA PLANTER.

THE GUM (*EUCALYPTUS*) DISEASE : ITS PROBABLE SALINE ORIGIN?

We received from Government a copy of Dr. Trimen's report on the new or rather newly developed disease, on Wednesday, but the pressure on our columns has been so great, that we had to defer the correspondence until today. It will be found on our last page. Much as we anticipated, would be the case, Dr. Trimen is, it will be seen, unable to trace the affection to either insect or to parasitic fungus. He describes the appearance of the leaf spots as exactly resembling the punctures of tree-bugs, but he must use the word "punctures" in a restricted sense, for there were and are no holes in the leaves such as result from the attacks of insects, certainly from attacks by *Helopeltis Antonii*, the Indian "tea-bug." He believes the disease to be an affection common always on leaves of jungle and other trees, aggravated this year by excessive wet and, perhaps, by unfavourable conditions of soil and drainage [Abbotsford is well drained, but the subsoil is no doubt in some places stiff, and the trees most affected are on high and exposed places. But the disease has appeared badly on places lower in elevation and without reference to condition of soil.] Dr. Trimen cannot adopt the belief which the Proprietor and the Manager felt compelled to receive and which they retain, that trees to leeward of gums are directly infected ; he does not regard gums as the source of the disease, although they are naturally, considering their origin, badly affected, and he decidedly answers "No" to the important question which we were specially anxious to have answered and settled "Will it be right to advise the extirpation of all gum trees." Our readers will be as much pleased as we are with this decision. It is clearly Dr. Trimen's opinion, and we see no reason to dissent from it, that if there had been no eucalypts in the country, the disease would have developed on cinchona and other plants, all the same, as the result of the abnormally wet season we have experienced. Individual planters must, however, observe and judge for themselves, whether blue gums are not specially liable to the disease and whether, when virulently affected, they are not agents of infection to cinchonas and other plants in their neighbourhood, especially if such plants be situated to lee of the gums in the South West Monsoon. Our experience of about four years leads to the affirmative conclusion.

Our readers will not be surprized to learn that Dr. Trimen does not commit himself to the recommendation of any curative treatment, topical or otherwise. There is only the inference to be drawn from the reference to possibly deficient drainage and its effects on the roots of the trees, which he was not able to investigate.

Observation on Abbotsford led so invariably to the result of tracing the commencement of this disease to the gums, the affection (if not the *infection* as we have felt justified in concluding, subsequently spreading to cinchonas on the lee side,) that we naturally adopted the name of "gum leaf-disease." Dr. Trimen objects to this and even to leaf-disease, which has locally been appropriated to the coffee fungus. A name must, therefore, be invented : "the wet canker" or something better. Coffee, which has its own special leaf-disease, has not, probably for that very reason, been attacked by the new affection ; and although the mature leaves of the tea trees have suffered, somewhat, we have seen no signs of canker in the stems or branches. One curious characteristic of the disease and which seems to shut out the idea of insect origin, is that mature leaves only are attacked and not the tender "flush."

We repeat, that we see no reason to question Dr. Trimen's conclusion that the disease would have developed even if no Eucalypts had been cultivated. But apart from experience at Abbotsford of the special virulence of the disease on gums and the apparent spread of the poison (whatever its nature) to leeward, there is the case of the vegetable gardens near St. Andrew's Hotel Nuwara Eliya. A gentleman who had seen it, year after year, yielding fine crops of vegetables, found, during a recent visit, cabbages, peas, beets, &c., all involved in one common ruin. "What is the matter?" he asked of the proprietor. "I cannot possibly conceive" was the reply. "The vegetables never suffered like this before." The visitor raised his eyes and saw leaf-diseased gum trees to the weather side of the garden. The idea of infection may, possibly, be baseless, but what are we to say to such a fact, especially in view of the other fact that the disease has not *yet* reached the "Lover's Leap" and places east of Nuwara Eliya? We shall anxiously watch the effects of the north-east monsoon.

* This is the first we have heard of the impertinent personality.—ED.

It is at least curious that coffee leaf-disease first appeared on the eastern side of the mountain, while this pest seems, as yet, confined to the western.

Dr. Trimen, whose scientific position is very eminent, may be right and we may be wrong on the question of the power of a badly affected tree to infect another; but if abnormal meteorological conditions are sufficient to set up a chemical action in the juices of a plant calculated to blotch and kill the leaves and to swell and canker the branches and twigs, so that many trees succumb, is there, we again ask, anything unphilosophical in the supposition that wind-carried drops of the diseased juices or particles of the diseased bark and wood tissues, may convey the disease to and infect previously healthy trees? As to the climatic conditions which produce the disease—apart from excessive moisture and the cold resulting from evaporation of that moisture, analysis of the rain water might have revealed something significant, had we only thought of testing it during the prevalence of the South-west monsoon. Abbotsford is nearer 60 than 50 miles, in a direct line, from the south-western seaboard, and there is, besides the distance, the objection of elevation (4,650 feet to 6,100) against the idea of sodium chloride being carried by the monsoon winds in sufficient quantity to inflict injury. While a moderate proportion of salt in the atmospbere is favourable to vegetation, which it stimulates, salt-storms can be deadly in their effects. Any one who doubts this has only to look at the young coconut palms on the seashore anywhere near Colombo. In the height of the south-west monsoon,

> When the wrathful spirit of storms
> Has made the tops of the waves his own;

and masses of bitter brine are carried inland, the leaves of the young palms are blackened and killed as if fire had passed over, and scorched them. The natives resort to very deep holes in order to shelter the young plants, but neither this expedient nor any other mode of shelter which would pay, as we know from experience, can prevent the destruction of a considerable per-centage of young coconuts annually, by that which is deemed, and no doubt correctly, beneficial to the palm when properly and moderately administered,—salt. Now sea water contains other salts besides sodium chloride, notably salts of magnesia, and we submit that it is just possible that an excess of *some* salt: ammonia, sodium chloride, magnesium chloride, or magnesium sulphate, in the atmosphere may have injuriously affected vegetation on our hills; the source of all, save the ammonia, being the ocean over which the winds had swept, absorbing moisture and with the moisture the salts contained in the sea, as they passed onwards or were drawn forwards? We are not dogmatizing, but throwing out suggestions for the consideration of those who have studied such subjects. The composition of sea water varies according to position and climate and for our purpose we look at the analysis of the water in the Bay of Bengal. In 1,000 parts, we get

Water	...	966·75
Sodium chloride	...	26·06
Magnesium do.	...	2·81
Potassium do.	...	1·20
Magnesium sulphate	...	1·82
Calcium	...	1·36

Most of the above ingredients would be rather beneficial than otherwise if properly applied. But they would be injurious in excess, and excess might be predicated of minute quantities applied for long-continued periods, as well as to over-doses given at once. In a most valuable book recently published (the Hand Book of Salt, second edition, by Dr. J. J. L. Ratton of the Madras Salt Department; Higginbotham & Co., Madras,) there are several accounts of damage inflicted on vegetation by salt storms, one of which occurred on April 29th of this year. It was a severe gale *from the South-West*, doing considerable damage to vegetation in the south of England for many miles inland. Its effects were attributed to salt, crystals of which were distinctly noticed. And now comes the statement to which we specially wish to direct attention. At a meeting of the Royal Horticultural Society, May 23rd, 1882, Dr. Church explained his experience on the subject of salt storms carried on for 15 years:—

"He found from 5 to 7 grains of salt per gallon of rain, brought from the west by autumnal gales; whereas ordinary rain water contained only half a grain to the gallon. He mentions that the exposed sides of the trees in Oakley Park were injured by the salt, which could be seen sparkling on the trees a few days after a gale, if no rain followed; and this at a distance of 25 miles from the sea. He thinks that *salt acts by abstracting moisture from the leaf cells, and forming a concentrated solution, which in a manner pickles the leaf.* Different trees were differently affected; but it was the general opinion of the meeting that this was *due to different degrees of hardiness in the trees.* Assuming that ordinary rain water in England contains half a grain of salt to the gallon, an inch of rain, would yield 11,315 grains per acre, and with an annual rainfall of 30 inches, 339,450 grains or 44lbs. per acre."

In an account in the Linnæan Transactions of a salt-storm which raged for several days in January 1803 the very word which Dr. Trimen uses as a synonym, for "canker" is applied to the effects of the wind-carried salt on vegetation, thus:—"The most remarkable phenomenon noted in connection with this storm, was that it *withered the leaves* of plants and MORTIFIED *their top branches* for a space of *seventy miles from the sea.*" This disposes of the difficulty of distance, for Abbotsford is not quite sixty miles inland.

But, once again,—let us look at the recorded effects of a salt storm in New England in 1815, and noticed in the *American Journal of Science*:—"At New London, Salem and other places, both on the coast and several miles in the interior, the leaves of many trees appeared as if they had been *scorched.*" And then comes confirmation of our position that the mischief might be the result of the long continued action of wind-carried moisture containing only minute portions of salt:—"The injury to plant life produced by salt storms, seems to be *in direct proportion to their intensity and* DURATION. It is a question of the *violent* [italics in the original,] application of salt-spray to plants, for a certain *length of time.*"

We submit that we have made out a strong case for at least the full investigation of our salt-spray theory of the new leaf-scorching and branch-and-stem-mortifying disease. Salt has undoubted merits in agriculture. But while a moderate application of this substance stimulates vegetation, there is no more deadly application to growing plants than salt in excess. "Gardeners and agriculturists are much better acquainted with its poisonous than with its fertilizing properties." Gardeners use salt to kill weeds and grass on pathways, and farmers employ salt in largest quantities for the improvement of weedy lands by the destruction of the weeds. Not even fire is destructive to vegetable tissue and plant-life.

If salt existed in the 56 inches of rain which fell at Abbotsford in the two months of June and July, at the rate of even 3 grains to the gallon, our readers can imagine what its *pickling* effects must have been, and quite consistent with the opinion of those who attended Dr. Church's lecture as to effect being in proportion to hardiness of tree, is the fact that while the delicate eucalypts and cinchonas have suffered

severely,* the robust tea plant has been but slightly affected. If, as seems to be the case, neither insect nor fungal origin for the new disease can be traced' we are surely justified in our suggestion of the possible excess of salts *of some kind*, in the copious and persistent rains of the past south-west monsoon, as the probable cause of the evil. If we are right, we may hope for the disappearance of the disease with the return of normal seasons.

The immunity from the disease of the vegetation on the east side of the island, if such immunity is a fact, would be quite consistent with our theory of mischief caused by a continued salt-storm from the south-west.

Sodium chloride in excess would quite account for the leaf affection, but the well known antiseptic properties of common salt may, to some, present a difficulty in tracing the branch and stem canker to the same agent. But some of the other salts may be the cause of mischief, or the cankering action may be set up in the branches and stems in sympathy with and as a consequence of the diseased, dying and dead condition of the leaves.

We may, in conclusion say, that except in very bad cases, cinchona trees, with us, have been saved by coppicing them well below the cankered portions. Topical applications, in the shape of lime, sulphur or carbolic acid we have not tried, the effects on coffee leaf-disease not having been sufficiently encouraging.

THE NEW PEST AND THE EUCALYPTS.

We place below the letter which led to Dr. Triman's recent visit to Abbotsford, and following it is the resulting report to the Government :—

Colombo, 19th October, 1882.

The Hon. the Colonial Secretary,

SIR,—I have the honor to request consideration by His Excellency the Governor of the suggestion, in a letter from my son, who is Resident Manager of Abbotsford Estate, Dimbula, that Dr. Trimen should visit the place in order to investigate and report on a disease which has developed with fatal effect on Australian Eucalypti grown for purposes of shelter, and which disease has spread to cinchona trees with equally disastrous consequences. If Dr. Trimen is unable personally to make the enquiry, he might perhaps depute Mr. Nock from Hakgalla. In either case the hospitality of Abbotsford bungalow would be extended, and my son would aid the enquiry to the utmost.

The following extract from a letter from my son will shew that the suggestion of a visit from Dr. Trimen was made by Dr. Duke, on the occasion of a visit to Abbotsford :—

"He came round with me to see the disease and he's awfully alarmed about it. He says that we'll be incurring a very heavy responsibility if we don't cut our gums down at once and warn other people. He says Dr. Trimen ought to be sent by Government to report on it. He thinks 90 per cent too low an estimate for the dead gums : he would almost say 100 per cent. I am sorry to say the young cinchonas are rapidly succumbing, after trying hard to shake it off. I feel that I am getting callous, as no one will take serious notice of the disease. Dr. Duke said he thought, like every one else, that we were making too much of it ; but now he declared we have not warned people enough."

As practically the whole of the many thousands of gum trees, which cost me large sums of money to introduce and cultivate, as shelter trees,—(thus following the advice I have, as journalist, earnestly pressed on the planters, especially the cinchona planters),—are dead, while the cinchona trees infected by them are dying, His Excellency the Governor will see that no prospect of personal benefit to myself is likely to arise from a visit from Dr. Trimen or his assistant. The question to be settled is whether the planters of Ceylon, at any rate those whose estates are situated at high altitudes and exposed to the south-west monsoon rains, should not be warned to eradicate the gum trees growing on their estates, with as much earnestness as they were formerly advised to cultivate them. I have given my son orders to eradicate every tree and burn every twig and leaf, having long struggled against what gives me much pain for other reasons than the pecuniary loss. But I naturally shrink from the responsibility of advising other planters to follow my example, unless assured that such advice is the best that could be given.

A gentleman in charge of an estate in Dimbula at a lower level by 1,000 feet than mine, wrote some time ago to ask my advice about this gum tree disease which had appeared on his trees and its probable effects on adjacent cinchonas. Diseased gum leaves have also been sent from an estate in the district of Dikoya and inspected by Mr. Staniforth Green, to whom I have repeatedly submitted specimens from Abbotsford ; but in no case has that gentleman any more than myself or my son been able to trace signs of either insect or fungic origin, although the late Dr. Thwaites when I first sent him leaves (about 4 years ago) spotted as if with smallpox (the spots gradually extending so as to involve the whole leaf), urged me me to look out for a bug. But during the four or five years existence and the recent rapid and fatal developement of the disease, no insects have been noticed at Abbotsford by night or by day. I have reason to believe that this disease on gum leaves and spreading from them to cinchonas, is far more prevalent than the reticence of planters would seem to indicate. Reticence in the matter is easily accounted for by the fact that but few are in a position to be able, without the dread of injurious consequences to their pecuniary interests, openly to state the existence of a pest which is calculated to alarm mortgagees or agents, regarding the value of estates as securities. But the judicious and discriminate removal of gum trees, as advised by a responsible official scientist, might be the best means of preserving the value of estates on which cinchonas are planted.

I have spoken of cinchonas as *specially* suffering from this disease, which first made its appearance on the Australian gums, but which unlike *hemileia vastatrix* in the case of coffee is not confined to one plant or species of plants, for tea bushes, roses, Australian acacias, and ornamental trees of many species grown in more or less proximity to affected gums, have been injured and sometimes fatally infected. In some respects, therefore, this gum leaf disease, whatever it may turn out to be, is even more formidable than the coffee leaf fungus.

The disease is said not to exist in Nuwara Eliya and its neighbourhood at altitudes considerably above Abbotsford. Of course an important object of the enquiry made by Dr. Trimen or his assistant, if the Governor agrees with me that enquiry is necessary and urgent, should be the conditions of soils, exposure, rainfall, etc., which appear to secure exemption from as well as those which seem to involve special liability to tthe disease. Abbotsford runs from 4,650 to 6,100 feet above sea level, and the shelter trees which have now been killed (in a season abnormally and persistently wet) by an obscure and apparently new disease, were specially needed as shelter from strong winds, and heavy rains. But

* In the case of the cinchonas themselves, immunity from the disease has been in proportion to relative robustness. The delicate Ledgerianas suffered most of all; then came officinalis; while succirubras were but slightly affected and the strong hybrids scarcely at all.

similar conditions and a clay subsoil are very general in Dimbulla and adjacent districts.

The Australian eucalypti although they grow generally in arid regions, yet specially flourish on the moist hill ranges of Fernshaw and Gippsland in Victoria, up to 4,000 feet altitude, which would be fully the equivalent of 5,000 or 5,500 in Ceylon.

As my sole object in this application is, if possible to secure the mass of Ceylon planters from the injury and loss which gum leaf disease has inflicted on myself, I need scarcely say that I anticipate the fullest publicity being given to this letter and such report as may result from it, should the Governor order enquiry and report.—I have the honor to be, sir, your most obedient servant,

A. M. FERGUSON.

Royal Botanical Gardens, Peradeniya,
15th Nov. 1882.

The Hon'ble the Colonial Secretary,

SIR,—With reference to my letter No. 61, of 27th October, and your reply No. 67, of Nov. 1st, I have the honor to inform you that the manager of Abbotsford estate having forwarded to me, before any application was made to him, specimens of the diseased leaves of eucalypts and other plants, I was able to make a full examination of them. But as it appeared desirable to see the diseased trees *in situ*, I proceeded in accordance with your request, to the estate itself and devoted a day to the examination of the growing plants and their surrounding conditions in company with the manager, Mr. A. M. Ferguson, junior. I brought away numerous further specimens and have since given to them as full an examination as I can afford :—

2.—From the letter to you (herewith returned) of the proprietor of Abbotsford, it appears that the points which he wished to have settled if possible was, whether the orders which he had given to his managers "to eradicate every (Eucalyptus) tree and burn every twig and leaf" were so well founded as to justify him (I presume in his capacity, as editor of a local newspaper) in "advising other planters to follow his example." The matter thus seemed to acquire a quasi-public character.

3.—The theory on which this radical treatment is based is this. The disease, which was first observed in gum trees on Abbotsford some four or five years ago, (soon after their introduction there) showed little severity and tendency to involve other kinds of plants till the present year. It has now, however, caused the death of many of the Australian eucalypts, and it is believed that these have "infected" the cinchona, tea, and other plants in "more or less proximity' to them, many of which have died in the same manner as the gum-trees after having first exhibited similar' spots on the leaves. It is the "malignant disease in the leaves," which thus become "the source of disease in other vegetation," that has principally attracted attention, and it is hoped that by the complete destruction of the eucalypts as soon as the spots appear, the disease may be kept from spreading to other plants in the vicinity.

4. In the endeavour to ascertain what truth there might be in this view, I first investigated the leaf-spots with as much care as I am able to give. They have precisely the appearance of being the result of puncture by some small suctorial insect, but, beyond their appearance, I cannot detect any sign of such being the case. I am assured that though carefully searched for, no insects of this sort (tree bugs) have ever been seen by any of several observers, nor could I find any myself. It is to be noticed too that it is very rarely that the young and delicate leaves are attacked, the spotting being in nearly all cases on the fully developed ones. As we have no evidence therefore of any insect foe, that explanation of the damage to the leaves may be abandoned.

5. The question of a parasitic fungus being the cause of the leaf-spotting is one more difficult of solution. I have carefully examined in a number of cases the spots in all stages, and the zone of thickened tissues surrounding the dead portion of older ones; but my results are purely negative. I believe I am correct in asserting that in these situations neither the mycelium nor fructification of any fungus are present; with the exception that upon the dried tissue one or two of the species which affect such situations are occasionally to be found. The spots commence as dark elevated points or pimples, the principal change occuring in the tissues being a morbid hypertrophy or thickening of the cell-walls and probably an increase of cell-production ; gradually the chlorophyll corpuseles disappear and the protoplasmic contents become more or less thick, opaque and of a brown or orange colour. Ultimately the cells dry up and die. The process spreads outwards from a central point, but does not extend far, resulting in a small depressed brown or white, circular spot of dead tissue surrounded by a slightly elevated border. The spot is generally perfectly circular and about 1-8th or 1-6th inch in diameter but two or three may coalesce. When the leaf is thin the centre often becomes perforated, and when the spot occurs on the harder tissues (e. g. the midrib) it present the appearance of an irregular ulceration.

6. It appears clear, therefore, that there are no elements to be found in these diseased leaf-spots which we can recognize as capable of conveying the disease from one plant to another. This could only be effected through the ageney of some parasitic animal or vegetable, neither of which is present. We are ignorant of any other means of infection. The manager of the estate endeavoured to demonstrate on the ground, that each diseased Gum-tree was a centre, and that of other plants, tea and cinchona for instance, the first to show spots were always close to the Gums and to leeward (i.e. North-East) of them, whilst the only plants that quite escaped were at some distance away or to windward. I was not however able to satisfy myself as to this constant relationship; the number of Gum-trees on the estate is very large and they are widely distributed, so that it is not difficult to point out one near and in the required direction. At the same time I cannot deny the *proximity* of the diseased plants to one another, but this is capable of a quite different explanation.

7. Were the leafspots the whole mischief not much harm would be done. I may say here that such spots are by no means new to me, nor, I should suppose, to any observant person in this country. They are frequently to be seen on both wild and cultivated plants, especially in cinchona. Some common jungle shrubs are almost constantly so affected. But at Abbotsford their abundant presence is unfortunately followed by and seems to be connected with more severe symptoms. I can only corroborate the truthfulness of the descriptions given by the proprietor and manager in their communications to the *Observer* as to the destruction of trees and shrubs that has occurred on this estate. In the eucalypts the younger branches and twigs shrivel and die back, a local decay of the stem near the top, usually accompanied by enlargement, occurs, and the portion above this perishes. I saw many trees of all ages with the upper part and lateral branches dead and dry whilst the main stem was yet alive and still endeavouring to put out new buds and branches. But a further development of the local "canker" soon appears lower down and before long the whole tree succumbs. In cinchonas the morbid phenomena are

much the same, the local "Canker" developes in the stem just below the last new growth. This swells and often causes a distortion or bend in the stem, the bark becomes dry and cracks, the cambium suffers and all above dies. In tea the appearance of the spots has not been followed by such serious disease; fortunately, too, the upper leaves are but slightly spotted. The few coffee bushes growing among these diseased species have almost entirely escaped, a remarkable fact, as I have elsewhere frequently observed coffee leaves with spots which I believe to be of a precisely similar nature.

8. In all this I am able to see only the outcome of some disturbance of nutrition, of a, so to speak, "constitutional" or general nature. I believe this condition to be not uncommonly developed in the *wet* districts of Ceylon, but it has not perhaps before been observed to exhibit so destructive a character. There is no sufficient evidence to shew that the Gum trees are responsible for it, though they have been the greatest sufferers. That they should be the first to succumb, is not very surprising when we consider that the species here grown are natives of the comparatively dry climate of extra tropical Australia transported to the very wet one of Lindoola. They seem to have early felt the change, and the exacerbation of the diseased condition in July last may be well ascribed to the unusually wet season experienced. The rainfall as ganged at the Bungalow, 5,800 feet was no less than 64·61 inches for the 3 months May, June, July, of which as much as 37·48 inches fell in July. The trees first destroyed occupied a situation fully exposed to the heavy S. W. monsoon rains and wind, at an elevation of nearly 6,000 feet, and those now rapidly dying crest a narrow and much exposed ridge. It is natural to suppose that these conditions which are the source of the sickness are localized in intensity by such causes as character and depth of soil, subsoil, aspect, drainage &c. In spots badly circumstanced in such respects, the disease will first shew itself, and affect the plants there growing in the order of their susceptibility. It is probable that the rootlets may be in an unhealthy condition; this I have however not made out, and it remains a subject for future enquiry.

9. In brief, then, I look upon the spots in the leaves as the first local manifestation of a disease of the general nutrition of the plant, and consisting in the death of the leaf tissues in small patches. (I think the term "leaf-disease" for this condition is liable to mislead since it has acquired a definite meaning in Ceylon restricted to a local parasitic malady). The mortification, or "canker," of the stems I regard as a later and more serious local development of the same diseased conditions, but it by no means always follows the leaf spotting. What is known of the real nature of the morbid states of plants (apart from parasitic diseases) is at present so little, that it would lead to no useful purpose to attempt any more definite explanation of that under consideration, nor am I inclined to give it any particular name. As above remarked, I think it to be an exaggeration of an unhealthy state common enough in Ceylon (and doubtless elsewhere) to a greater or less extent, but usually passed without special notice. A full knowledge of its actual nature could not fail to throw great light on vegetable pathology, but the necessary work would have to be done by skilled specialists with ample leisure.

It is not possible to suggest any well founded treatment, but, as regards the principal point of practical procedure which suggested this enquiry, I must say that in my opinion the wholesale destruction of all species of eucalyptus is not warranted by our present knowledge nor is likely to ensure the protection of other plants from the disease if still exposed to the local conditions which seem to be its cause,—I am, &c., (Signed) HENRY TRIMEN, *Director.*

RABBITS IN NEW ZEALAND.—Some idea of the magnitude of the rabbits evil (says the "Matnra Ensign") may be gathered from the fact that the New Zealand Agricultural Company lay down on their various runs in the district, no less than 40,000lb. of poisoned grain, monthly.—*Fiji Times.*

POTATOES IN FIJI.—An excellent sample of potatoes has been forwarded to this office by Mr. W. Fisher, of Wairiki, Taviuni. It represents the product from one haulm and in quality, size and quantity, it is all that could be desired. Mr. Fisher says: "I have been digging potatoes from the small patch I planted for over two months, and the yield has been the same throughout. I forward them that you may see how potatoes will do in Fiji, if planted in the proper season."—*Fiji Times.*

PEAT LITTER.—Mr. Sowerby, writing to the London *Times* upon the subject of peat litter, remarks that its use in stables is much on the increase. Several of the tram companies, and the Zoological Gardens, Regent's Park, employ it to a large extent, and speak very highly of its efficiency and small cost. After it has served the purpose of "litter," it is found in the Botanic Gardens very valuable as a rich and handy compost and manure, being easy of carriage and manipulation.—*Gardeners' Chronicle.*

FRUIT EXPORTS FROM FIJI.—For Fiji fruits as for Fiji sugar the Australian colonies offer a near and profitable market, and the local paper states:—"The steady increase in the exportation of fruits which, from £97 10s in 1875, has rapidly advanced year by year to the maximum amount of £5,469 19s in 1881, is only an evidence of what might be achieved if means of transport could be secured. This will follow in time, and will open up a practically, illimitable source of wealth to the producers."—*Fiji Times.*

SUGAR IN FIJI.—A splendid sample of sugar has been forwarded to this office from the Penang mill, and it is pronounced by competent judges to be equal, if not superior, to any that has hitherto been turned out in the colony. It is an exceptionably large white crystal, worth between £36 and £37 per ton in the local market, and its fault, if it has one, is that the crystals are too large for ordinary purposes. The sample is well worth inspection as indicating the quality it is possible to turn out, and it has already attracted a very considerable amount of attention.—*Fiji Times.*

A PRESERVATIVE AGAINST WHITE ANTS was thus noticed in the proceedings of the Madras Horticultural Society:—"Read the following circular from Mr. Woodrow, Superintendent, Botanical Garden, Gonesh Khind, Poona:—*Perchloride of Mercury*, as its name implies, is a compound of clorine and mercury. It is a heavy white crystaline substance soluble in water and very poisonous. It is procurable from any chemist in a large way of business. This substance has been in use during many years among botanists and other naturalists to protect their specimens from insects, and recently has been tried with success against white ants. To use the perchloride of mercury it should be dissolved in water and the papers to be preserved dipped in the solution: glass or glazed-ware vessels only should be used to keep the solution. As some officers meet with a difficulty in getting this substance, a small quantity has been prepared at this office for distribution; it is packed in small packets, each sufficient for one quart bottle of water, and these packets are enclosed in a paper, bearing directions for use and containing one dozen packets; two dozen packets, sufficient for two dozen bottles of solution, will be sent post free for R1; smaller quantities cannot be supplied at this rate."

Correspondence.

To the Editor of the Ceylon Observer.

PLANTING POSITION AND PROSPECTS OF TRAVANCORE.

Travancore, 14th October 1882.

DEAR MR. EDITOR,—Being a regular reader of your much esteemed and admirably got-up *T. A.*, I have often wondered how you got such a searching and exhaustive periodical through the press without, at times, getting a snack of news from this, not far distant, but much-maligned, country. There are many here in a much better position to supply you with the news of the place than I am. However, in the absence of anything better for the present, I trust you will excuse the liberty I am about to take in asking you to accept a few lines from my but scantily informed pen.

Our chief produce, coffee Arabica, has, similar to Ceylon, greatly lost favour with us lately, but from the fact that a few new clearings have been planted this last planting season, with this product, it does not appear that planters have *altogether* lost faith in it yet. I think I may safely say that this much abused product may yet, with proper management, be induced to pay *a little*. Of course the good old times are over, and capitalists should not be disappointed if they cannot now make fortunes such as have been made in former times. When I say proper management I mean, if young plants for new clearings are raised from seed procured from properly matured, well-nourished and vigorous plants, instead of being taken from amongst the old coffee—as plants for new clearings have, in the majority of cases, been done over here—if new clearings are felled with proper attention to aspect, elevation and soil, and, last but by no means least, trees and belts being left for shade and shelter where required, and if due attention is paid to the *necessity* for efficient and economical cultivation. We all look forward to the time when the carbolic acid treatment, after having had a fair trial, shall be pronounced a failure or success. None of us, however, have ventured on a trial of this new mode of entertaining *H. V.*

New Products and their results we all look dorward to more or less; but we have not plunged into them with the same sanguine vigour many of our Ceylon friends have, for the chief reason that imany of us have not the money to spare.

Cinchona is having a fair trial, and on some estates very fine cinchonas 2 years old may be seen. No one as yet has ventured to shave or bark their young cinchona. I may mention that a sample of *C. succirubra* bark taken from trees 10 or 12 years old grown at an elevation of 3,000 feet on *Upper Victoria* fetched 2s 9d per lb. in the London market lately.

Cacao has had an extensive trial more or less; and although it has occasioned loss and disappointment, there are a few plants flourishing in evidence of some enterprizing attempts to grow this product. We have not however been altogether discouraged from trying to grow this *fickle* plant, as a lot of plants were put in this last season. An old planter here, who has had a few cacao trees growing on his estate for "ages," got a very favourable report of a sample he sent *home* lately. On the strength of this report he has been extending his little patch of cocoa.

Tea is very little thought of over here except by one or two. I believe the reason for its being so little thought of, is because so few know little or anything about the plant and its capabilities. There are two estates at the extreme south end of the range, each owning an acre of a very good kind of tea. (I have heard this tea styled "Assam Indigenous"; others again say it is only a very fine *hybrid*. However, let it be what it may, one acre, which was planted some 10 or 12 years ago, 5 feet ×6 feet, and in which there are a good few vacancies, gave one year 370 lb. prepared tea and the next 350 lb. This acre of tea is in most wretched soil and at an elevation of 3,500 feet above sea level.) Seed from this tea is being taken and endeavours are being made to extend the planting of this valuable tea by the fortunate possessors as much as possible. This and a little tea planting in the north are, I am sorry to say, the only endeavours I know of to go in practically for this new product.

Rubber is being a little thought of. There are, however, only two estates that I know of, which possess rubber planted out in the field and growing. There are one or two others, however, who have the *product* in their nurseries. The kind gone in for is Ceara.
